All patients had received cranial irradiation. Single-agent or combination chemotherapy had been administered before the development of PCP in seven episodes (Table 1), including a nitrosourea (lomustine, PCNU [1-(2-chloroethyl)-3-(2,6 dioxo-3-piperadyl)-1-nitrosurea], or carmustine), procarbazine hydrochloride, vincristine sulfate, fluorouracil, hydroxyurea, mechlorethamine hydrochloride, and misonidazole. None of the five patients who received a nitrosourea had documented pulmonary toxic reaction from the agent. None of the patients had an identified human immunodeficiency virus risk factor other than one patient, who had had a blood transfusion between the first and second episodes of PCP. One patient had received trimethoprim-sulfamethoxazole for a urinary tract infection 3 months before the diagnosis of PCP.

All of the patients with PCP were receiving dexamethasone (Table 1). The duration of steroid therapy before the onset of PCP symptoms ranged from 5 weeks to 9.5 months (median, 2.75 months). The onset of symptoms in eight of the 11 episodes occurred while dexamethasone therapy was being tapered. The interval from the initiation of the tapering of steroid therapy to onset of PCP symptoms in these eight ranged from 1 to 63 days (median, 12 days). At the time of diagnosis of PCP, daily dexamethasone dose ranged from 2 to 60 mg.

Table 1.—Relationship of Steroid Therapy and Chemotherapy to PCP*

Episode (y)	Maximum Dosage of Dexamethesone, mg/d	Duration of Dexamethasone Therapy Before Symptoms of PCP, mo	Duration of Dexamethasone Taper Before Symptoms of PCP, d	Dexamethasone Dosage at Diagnosis of PCP, mg/d	Chemotherapy
1 (1982)	32	1.5	. . .†	8	Carmustine, hydroxyurea
2 (1982)	24	2.5	63	2	Lomustine, fluorouracil, misonidazole
3 (1983)	28	1.5	. . .†	20	None
4 (1983)	92	2.25	5	24	None
5 (1984)	24	9.5	21	12	PCNU
6 (1985)	32	3.0	17	12	Fluorouracil
7 (1986)	100	1.25	11	4	Mechlorethamine hydrochloride, vincristine
8 (1986)	24	3.25	1	8	Lomustine, vincristine, procarbazine
9 (1989)	48	3.25	14	32	None
10 (1989)	16	2.75	5	10	None
11 (1989)	96	4.25	. . .†	60	Carmustine

*PCP indicates *Pneumocystis carinii* pneumonia. Only those drugs in use at the time of the diagnosis of PCP are listed.

†Episodes occurring in the absence of a steroid taper.

Table 2.—Clinical Summary of 11 Episodes of PCP in Patients With Brain Tumors*

Episode	Symptoms	Duration of Symptoms Before PCP Diagnosis, d	(A-a)O_2 Gradient, mm Hg	LDH, U/L	Chest Roentgenography at First Evaluation of Symptoms	Outcome
1	NC, F	14	53	510	Bilateral infiltrates	Recovered
2	NC, D, F, CP	1	69	960	Bilateral infiltrates	Recovered
3	NC	14	73	672	Focal infiltrate	Recovered
4	PC, D, CP	1	51	336	Diffuse infiltrates	Recovered
5	D, F	7	215†	803	Bilateral infiltrates	Died
6	PC, D, F, CP	3	54	820	Focal infiltrate	Died
7	NC, D, F	30	. . .	1284	Diffuse infiltrates	Recovered
8	NC, D	22	35	419	Normal	Recovered
9	D	7	76	480	Diffuse infiltrates	Died
10	NC, CP	3	23.5	409	Bilateral infiltrates	Recovered
11	NC, D, F	10	. . .	499	Focal infiltrate	Died

*PCP indicates *Pneumocystis carinii* pneumonia; (A-a)O_2, alveolar-arterial oxygen; LDH, lactate dehydrogenase; NC, nonproductive cough; F, fever; D, dyspnea; CP, chest pain; and PC, productive cough.

†Patient receiving supplemental oxygen.

Table 2 summarizes the clinical presentations of the 11 episodes of PCP. At the time of diagnosis of PCP, pulmonary symptoms had been present from 1 to 30 days (median, 7 days). The most common presenting symptoms were dyspnea in eight cases and a nonproductive cough in seven. Fever was present in six of the episodes. In nine episodes in which an arterial blood gas value was obtained, an increased alveolar-arterial oxygen tension gradient (range, 23.5 to 215 mm Hg; median, 54 mm Hg) was present. One arterial blood gas value was obtained from a patient receiving supplemental oxygen (episode 5, Table 2). Elevated lactate dehydrogenase (LDH) levels ranged from 336 to 1284 U/L (median, 510 U/L), and were present in each episode. Serum albumin level ranged from 24 to 38 g/L. Total leukocyte count at diagnosis of PCP ranged from 3.5 to 14.4×10^9/L, and absolute lymphocyte counts ranged from 0.17 to 2.3×10^9/L (median, 0.28×10^9/L; lower limit of normal is 1.0×10^9/L). Chest roentgenograms at the time of the initial pulmonary evaluation showed either no infiltrate (episode 8), or infiltrates that were focal, bilateral (multifocal), or diffuse. A cavitary lesion in addition to infiltrates was seen in one case (episode 3).

Fiberoptic bronchoscopy was diagnostic in each of the eight cases in which it was performed. Bronchoalveolar lavage analysis was positive for PCP in six of eight patients. A transbronchial biopsy specimen was positive in three of the six patients who had this procedure. Two patients (episodes 10 and 11) were found to have more than one pulmonary pathogen. The first patient (episode 10) underwent bronchoscopy because of a nonproductive cough, chest pain, and a persistent infiltrate on chest roentgenography. *Pneumocystis carinii* was found in the bronchoalveolar lavage, and fungal elements consistent with *Aspergillus* sp were found invading blood vessels in the transbronchial biopsy specimens. The second patient (episode 11) had autopsy lung cultures and histologic findings consistent with cytomegalovirus infection as well as PCP. Three patients did not undergo bronchoscopy but received diagnoses at autopsy. One of these (episode 5) had a fulminant clinical course and died on the day of admission before any procedure could be carried out; the second (episode 9) was taking anticoagulants and died before the prothrombin time returned to normal, preventing bronchoscopy; the third (episode 11) was moribund from progressive tumor when pulmonary symptoms began, and at the family's request, bronchoscopy was not performed.

Ten episodes were treated with intravenous trimethoprim-sulfamethoxazole. None of these patients had an adverse reaction to therapy. All were receiving dexamethasone throughout therapy.

Four patients (40%) died of PCP. Six patients survived seven episodes of PCP; five subsequently died of their tumors.

Forty Patients Without PCP

It is difficult to determine the exact incidence of PCP in a setting in which patients are often seen in initial evaluation and then referred back to their point of origin while still receiving corticosteroid therapy. Five hundred eighty-seven adult patients with primary brain tumors were seen for therapy at MSKCC from 1981 to 1989. The records of 40 patients from this group were reviewed to determine how many received ongoing treatment there. Four did not receive therapy at MSKCC or had less than 1 month of follow-up. Therefore, we estimated that 90% of the total study group had received ongoing treatment. This would make 1.7% a least estimate of the percentage of patients in whom PCP developed. All 40 patients received steroid therapy, with durations (to discontinuation of steroid therapy or to last follow-up) ranging from 3 weeks to 28 months (median, 3.8 months).

COMMENT

The association between PCP and the use of high doses of corticosteroids is well documented. Data available in the literature suggest that steroids permit reactivation of latent infection by suppressing the immune system of the host.[9,10] Cellular immunity seems to play the predominant role in the host's defenses against PCP. Many of the underlying diseases in patients with PCP have associated defects of cellular immunity.[1-5] Cyclosporine[11] and dexamethasone both predispose patients to PCP and both inhibit T-lymphocyte proliferation by mechanisms affecting interleukin 2 (T-cell growth factor), a T-helper cell product.[12,13] Single doses of glucocorticoids in humans have been shown to induce peripheral lymphopenia, probably by redistribution of lymphocytes from the circulation into other body compartments.[14] None of our patients had tests of immunologic function, but peripheral lymphopenia was present in all for whom this information was available.

Paradoxically, PCP often becomes clinically apparent when steroid doses are being decreased or withdrawn. Animal studies suggest that a tapering of steroid therapy may simply unmask *P carinii* infections that have developed earlier during high-dose steroid administration. In a rat model, steroids have depressed the capability of the host to mount an inflammatory response to *P carinii* infection. This inflammatory response appears as the steroid dosage is decreased.[9] Those rats receiving high-dose steroids in which PCP developed had scanty alveolar exudates despite the presence of *P carinii* organisms in the lung tissue. When steroids were withdrawn or tapered, intense inflammatory exudates developed. Similarly, rabbits on long-term, stable steroid doses suffer PCP without the characteristic proteinaceous alveolar exudate and interstitial plasma cell infiltration.[10]

Multiple human studies have confirmed the relationship between decreasing steroid doses and PCP. Fossieck and Spagnolo[6] observed the appearance of PCP in patients with lung cancer who were receiving tapering doses of steroids. Other investigators have found that of 19 children with cancer in whom PCP developed, 17 had recently had steroid administration discontinued or were receiving low-dose replacement therapy when the diagnosis of PCP was made.[15] Singer et al[16] reported the occurrence of PCP in 11 patients (10 with lymphoma or leukemia) who had received steroid therapy. In seven of these patients, PCP developed in the setting of a tapering of steroid therapy. In our series, eight of 11 episodes of PCP occurred during a tapering of steroid therapy. The duration of the tapering of steroid therapy before the onset of pulmonary symptoms ranged from 1 to 63 days, but seven of the episodes occurred within 21 days of initiation of the tapering.

In all prior studies, PCP was rare among patients with solid tumors. Our findings, however, suggest that this disease occurs in a subset of patients with solid tumors, namely, those with brain tumors. The increased incidence of PCP in patients with primary brain tumors is most likely due to the fact that they frequently receive high-dose corticosteroids for extended periods. Patients with solid tumors that do not arise in the central nervous system who are placed on similar steroid regimens may also be at risk for PCP. In the only other published series of patients with solid tumors who had PCP, three of five patients with lung cancer who had PCP had received dexamethasone for brain metastases, followed by a tapering of steroid therapy.[6]

Clinicians should have a high index of suspicion for PCP in this selected patient population, particularly because the clinical presentation of PCP can be subtle and nonspecific. Patients with mild pulmonary symptoms in whom the diagnosis of PCP is suspected should be screened carefully. If the chest roentgenogram shows diffuse infiltrates, bronchoscopy should be done emergently. If the chest roentgenogram is normal and the patient has mild symptoms, other sensitive tests might be helpful to detect interstitial lung disease. These tests include pulmonary diffusing capacity,[17,18] rest and exercise arterial blood gas values,[19] or performance of a gallium citrate lung scan.[20] If any of these test results are abnormal, one should proceed to bronchoscopy. A serum LDH measurement may be useful. All the patients in this study had elevated levels of LDH. A previous report on patients with acquired immunodeficiency syndrome (AIDS) who had PCP found that only 7% had normal LDH levels, and levels greater than 450 U/L were highly specific for PCP.[21] In this same study, six (75%) of eight patients without AIDS with PCP had elevated LDH levels. Further investigation is required to determine the sensitivity and specificity of this test in the population without AIDS. Confirmation of the diagnosis of PCP depends on the demonstration of the organisms either in lung tissue or in bronchoalveolar lavage fluid.

If abnormalities consistent with the diagnosis are found in any of the above tests, further evaluation with bronchoscopy, including bronchoalveolar lavage[8,22] and transbronchial biopsy,[23,24] is recommended. In more acutely ill patients, bronchoscopy is recommended to make the diagnosis as rapidly as possible. If bronchoscopy is nondiagnostic, the decision as to whether the patient should have an open-lung biopsy, close follow-up, or empirical therapy depends on the clinical status of the patient and the physician's index of suspicion.

In a prospective, randomized study of children with hematologic malignant neoplasms, trimethoprim-sulfamethoxazole provided excellent protection against PCP with minimal toxic reaction.[25] In a second study of this population, trimethoprim-sulfamethoxazole prophylaxis had equal efficacy when administered for 3 consecutive days each week when compared with a daily regimen.[26] Although the risk of PCP in these studies was much higher than in our patients (PCP developed in 17 of the 80 patients in the placebo-treated group), our findings suggest that prolonged administration of high doses of steroids in patients with brain tumors substantially increases the risk of PCP.

Patients likely to need prolonged, high-dose steroid therapy include those with large postoperative tumor burdens, those in whom steroid dependence develops during radiotherapy, and those with unresectable brain-stem lesions. Such patients undergoing tapering of steroid therapy are a high-risk subgroup. Given the high mortality of 36%, trimethoprim-sulfamethoxazole prophylaxis should be considered for such patients.

Neuroanatomic Differences Between Dyslexic and Normal Readers on Magnetic Resonance Imaging Scans

Ranjan Duara, MD; Alex Kushch; Karen Gross-Glenn, PhD; W. William Barker, MS; Bonnie Jallad, MS; Shlomo Pascal, MD;
David A. Loewenstein, PhD; Jerome Sheldon, MD; Mark Rabin, PhD; Bonnie Levin, PhD; Herbert Lubs, MD

• The areas of six bilateral brain segments in the right and left hemispheres, on a horizontal brain section, and the area of subdivisions of the corpus callosum, on a midsagittal brain section, were measured on magnetic resonance images obtained from 21 dyslexic and 29 control subjects. In the entire group, the frontal half of the horizontal brain section showed asymmetry, with the right side being larger, whereas posteriorly only the occipital polar segment was asymmetrical, with the left side being larger. Dyslexic subjects exhibited asymmetry, with the right side greater than the left side, in contrast to the relatively symmetrical pattern that is normally observed in the midposterior segment that corresponds to the angular gyrus. In the corpus callosum, dyslexic subjects were found to have a larger splenium than nondyslexic subjects, and dyslexic female subjects were found to have a larger splenium than dyslexic male subjects. Because transcallosal pathways connecting the left and right angular gyrus regions traverse through the splenium of the corpus callosum, the above findings in dyslexic subjects suggest an anatomic abnormality in the angular gyrus region.

There now exists a strong body of evidence that the human cerebral hemispheres are morphologically asymmetrical in adults as well as in children.[1] As a discrete structure in the brain, the posterior portion of the superior temporal plane (the planum temporale) shows an impressive left-greater-than-right asymmetry, but other structures, such as the frontal lobes, have also been shown to be consistently asymmetrical at a macroscopic level.[1] Cytoarchitectonic studies show asymmetries with greater neuronal density on the left side in the inferior parietal lobe,[2] the left auditory cortex,[3] and the posterior portion of the thalamus.[4]

Some of these morphologic asymmetries may be linked to functional differences between the hemispheres. For example, it has been postulated that because the left planum temporale, which is located in Wernicke's area, is larger than the right in 65% of adult brains, the larger left planum is in some way related to left hemispheric dominance for language.[5,6] Furthermore, neuropathologic studies in four adult dyslexic subjects who have exhibited symmetry of the plana temporale, rather than the usual asymmetry, also suggest an association between the relative asymmetry of this structure and functional abilities in the language domain.[7] Direct evidence linking anatomic asymmetries to language laterality or other functional differences between the two hemispheres, however, is still lacking.[8,9]

Geshwind[10] suggested that the information obtained from studies of cases of acquired dyslexia could be useful to obtain an understanding of the neurologic basis of developmental dyslexia. In this regard, it is clear, beginning with the earliest studies of Dejerine,[11] that lesions in the left angular gyrus are associated with alexia, among other findings. More recently, Benson[12] categorized alexias, by the sites of the causative lesions and the clinical presentations, into posterior alexia (occipital alexia or alexia without agraphia), central alexia (parietotemporal alexia or alexia with agraphia), and anterior alexia (frontal alexia or motor alexia associated with Broca's aphasia). In addition to the left angular gyrus, the medial occipital lobes, and Broca's area, the splenium of the corpus callosum has also been implicated in posterior alexia.[13] (Studies involving reading-disabled children show evidence of inefficient interhemispheric transfer of visual information, which would also suggest that the splenium of the corpus callosum may be at fault.[14,15])

Several neuroimaging studies, with the use of computed tomography (CT), have suggested reduced or reversed asymmetry of the posterior aspects of the cerebral hemispheres in dyslexic subjects,[16-18] although one nonquantitative magnetic resonance imaging (MRI) study has failed to demonstrate any anatomic differences between dyslexic and normal subjects.[19] (For a review of these studies, see Hynd and Semrud-Clikeman.[20])

Planes that cannot be imaged by CT, such as the sagittal plane, can be visualized on MRI scans. With the advent of MRI, it has become possible to obtain much improved definition of neuroanatomic structures. In this study, we compared groups of well-defined, right-handed male and female subjects and dyslexic and normal readers on measures of cerebral anatomic asymmetry and corpus callosum size, obtained by area measurements on MRI scans. Area measurements constitute an advance over previously reported linear measurements, although true volumetric analysis would have been preferable. This was deemed impractical for this study because three-dimensional reconstruction of anatomic regions was not available to us with the system that was used.

We chose to segment the brain into six pairs of areas that corresponded to brain regions of interest to define the location of these asymmetries. A single section in the horizontal plane, at the level of the foramen of Monro, includes most brain regions that are considered important for reading and language.[13] Previous studies have involved evaluation of brain asymmetries via transverse linear measurements at arbitrarily chosen points along the anteroposterior dimension of the brain. In this study, we categorized the brain regions where these asymmetries were most prominent and where they best discriminated between groups of subjects, ie, male vs female subjects and dyslexic vs normal readers. Based on previous neuroimaging findings in subjects with developmental language disorders,[16-18] the working hypothesis in this study was that one or more brain segments in the posterior half of the brain would show aberrant asymmetry in dyslexic subjects.

METHODS

MRI

Magnetic resonance imaging was performed with a superconducting whole-body scanner (Siemens Magnetom, Iselin, NJ) (1.0 or 1.5 T) with use of a 25-cm-diameter head coil. Sections were 7.0 mm thick, with 3.0 mm intersection intervals with use of a 256 × 512-pixel matrix. Three sagittal T_1-weighted spin-echo sequences (repetition time, 500 milliseconds; echo time, 17 milliseconds) were obtained with the central section positioned through the midline. Transverse T_2-weighted spin-echo sequences (repetition time, 2500 milliseconds; echo time, 25 and 90 milliseconds) provided 13 sections that were obtained parallel to the inferior orbitomeatal plane with one section transecting the foramen of Monro. The correct plane was ensured by appropriate positioning of the patient before the study began. The measurements on the horizontal section were performed on the T_2-weighted image, with an echo time of 25 milliseconds (proton density image).

Measurements

All measurements were made with a planimeter on brain outlines derived from hand tracings of MRI scans.

Horizontal Areas.—Horizontal area measurements were made from transverse MRI scans at the level of the foramen of Monro. This section is anatomically very similar across subjects in that it transects the basal ganglia, thalamus, and the four tips of the lateral ventricle horns (Fig 1). This section is very informative for this study, as it includes parts of the prefrontal and premotor lobules of the frontal lobe (including Broca's area), the superior temporal gyrus, the inferior parietal lobule, and the cuneus and lateral cortex of the occipital lobe (level 6 in the brain according to the atlas by Eycleshymer and Schoemaker,[21] which is also sectioned in the inferior orbitomeatal line).

The brain was traced along the inner table of the skull, and a line was drawn along the interhemispheric fissure following its contours. The anterior and posterior limits of this line were determined as the points at which there was divergence of the medial outlines of each hemisphere in the frontal and occipital regions. The length of the interhemispheric line was based on the linear distance between these two points. The segmentation of the brain (see below) was based on the linear distance, but the area measurements were performed with the contoured medial border, which was the interhemispheric fissure. The interrater reliability of the placement of the anterior and posterior limits of the interhemispheric line was determined by having two raters (R.D. and A.K.) determine these points on tracings of the brain and measure the distance from these points to a fixed point. The correlation coefficients were .95 and .98, respectively, for the anterior and posterior limits. Lines were drawn perpendicular to the midline at its midpoint (50% line) and at 10% and 30% distances from the anterior and posterior limits, dividing the brain into six pairs of right- and left-sided brain segments (Fig 1). These segments were designated anterior polar 10%, midanterior 20%, anterior central 20%, posterior central 20%, midposterior 20%, and posterior polar 10%. Each area measurement was made three times, and the mean value was used. Interrater reliabilities for these mean values among three raters were $r = .98$ and $r = .99$. On the lateral surface of the brain, the cerebral cortex in the anterior polar 10% corresponded approximately to prefrontal regions; midanterior 20% to premotor regions, including Broca's area; anterior central 20% to the insular cortex and the anterior part of the superior temporal gyrus; posterior central 20% to the plana temporale (or the posterior part of the superior temporal gyrus) and the supramarginal gyrus of the inferior parietal lobe; midposterior 20% to the angular gyrus; and posterior polar 10% to the lateral occipital cortex and the cuneus of the occipital lobe. This correspondence of anatomic brain regions to the segments used in this study was ascertained by segmentation of the brain section at the appropriate axial level (level 6) according to the atlas by Eycleshymer and Schoemaker.[21] It was then possible to determine, on both the lateral surface of the brain, provided in the atlas, and on the horizontal section, the brain regions encompassed by each segment. The area of each right and left half of the individual segments contributed the primary data for this analysis.

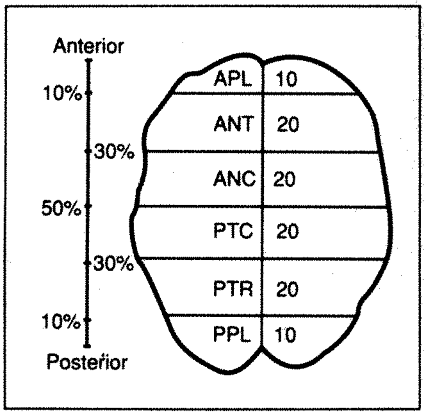

Fig 1.—Drawing of horizontal brain section in dyslexic subjects and nondyslexic subjects with the location and extent of each of six segments. APL indicates anterior polar; ANT, anterior; ANC, anterior central; PTC, posterior central; PTR, posterior; and PPL, posterior polar.

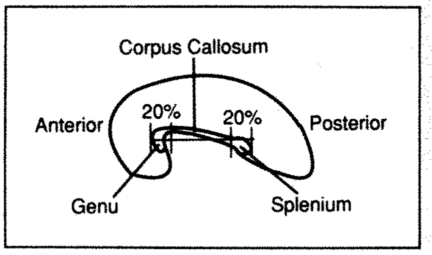

Fig 2.—Drawing of sagittal brain section, with depiction of the outlines of the corpus callosum and its subdivisions and the midsagittal brain area.

Corpus Callosum Areas.—Corpus callosum measurements were made from sagittal MRI scans of the midsagittal plane. The corpus callosum was traced directly. The midsagittal brain area was traced by following the superior border of the corpus callosum from the genu to the splenium and then following the cerebrum posteriorly along the inferior border of the occipital lobe and continuing anteriorly over the convexity of the brain and finally posteriorly along the inferior border of the frontal lobe until the genu was reached again (Fig 2). The corpus callosum was divided into fifths along a line joining the most anterior and posterior points on the genu and the splenium, respectively. Area measurements were made of the total corpus callosum, anterior fifth or genu, and posterior fifth or splenium. Each callosal area was normalized to and expressed as a percentage of the midsagittal brain area to control for individual differences in brain size.

Informed consent was obtained from each participant in the study after the procedures were explained. Each prospective subject underwent a clinical interview to obtain information pertinent to diagnosis (ie, developmental, family, and educational history). As dyslexia is thought to have a heterogeneous origin, we sought to minimize variability among dyslexic subjects by confining our sample to individuals with a clear family history in first-degree relatives and to those with no known prenatal or perinatal condition that might yield learning problems. Because of the frequent overlap in the population between dyslexia and attention-deficit–hyperactivity disorder (ADHD), we did not exclude dyslexic subjects who also reported a childhood history of ADHD, for practical reasons. To do so would have added an unacceptable restraint to the subject recruitment process. The stringent criteria for reading and spelling deficits (see below) ensured that no dyslexic subjects had purely ADHD. However, to ensure the normalcy of our control group, normal readers with a history of ADHD or any other learning disability were excluded.

Table 1.—Subject Characteristics

Variables	Mean ± SD Dyslexics	 Nondyslexics

#Nonsense Passage Reading (standard scores).[25]

A total of 50 right-handed adults participated in the study (Table 1). This study group included 21 dyslexic (12 male and nine female) and 29 nondyslexic (15 male and 14 female) subjects. Handedness was measured by the Edinburgh Handedness Inventory.[22] Groups were matched as closely as possible for age and years of education (Table 1). Because of the disadvantage that dyslexic subjects experienced in acquiring an education, there was a significant difference in the educational levels of the two groups, but all dyslexic subjects were of average to high-average intelligence (Table 1). The diagnosis of developmental dyslexia was made if all the following conditions were met: (1) a 1.5-SD discrepancy on reading and/or spelling tests vs IQ was verified; (2) there existed a history of childhood reading and spelling problems; and (3) there existed a family history of dyslexia in at least two generations.

Dyslexic subjects scored significantly lower than nondyslexic subjects on oral reading of meaningful text (Gray Oral Reading Test[23,24]; $P<.02$) and Nonsense Passages[25] ($P<.001$). Both groups comprised native English-speaking subjects who had neither neurologic nor psychiatric disorders, all of whom reported having had adequate educational opportunity for learning to read.

Severity Scores.—A group of dyslexic subjects (n = 16) was rated on a severity score based on differences on standard scores of full-scale IQ (Wechsler Adult Intelligence Scale-Revised)[26] and certain reading and spelling tests. The severity score comprised the average of three components: (1) full-scale IQ–Gray Oral Reading Test, (2) full-scale IQ–Wide Range Achievement Test (Spelling),[27,28] and (3) full-scale IQ–Average of Nonsense Passage Errors and Trials. The higher the severity score, the greater the relative impairment in reading and spelling.

DATA ANALYSIS

Horizontal brain areas were obtained for the right and left segments of the anterior polar, anterior, anterior central, posterior central, posterior, and posterior polar regions and analyzed with a multivariate analysis of covariance approach. Diagnosis (dyslexic vs normal readers) and gender (male vs female subjects) served as independent grouping factors, while hemisphere (right vs left) was treated as a repeated measure. Because of large individual differences in brain size, total brain area was entered as a covariate in this analysis. A covariate approach was adopted rather than entering normalized measurements into the multivariate analysis of variance equation, as the latter approach would confound the variance-covariance matrix and create extensive interdependence between measures (scores for each patient would necessarily add up to 100% with the use of normalized measures), thus violating necessary assumptions required for these analyses. Whenever significant, multivariate analysis of covariance main effects and/or interactions were obtained ($P<.05$), subsequent univariate analyses of variance (ANOVAs) were then examined. Because of multiple ANOVA contrasts, a more conservative criterion of $P<.01$ was set for each univariate analysis.

To examine the relationship between severity scores and brain areas, whenever a brain segment indicated a significant main effect or interaction on the multivariate analysis of covariance, further analyses utilizing Spearman rank correlations were performed between severity scores and brain segment areas. Again, due to multiple comparisons, the criterion for significance was set at $P<.01$.

Corpus callosum area measurements were analyzed with the use of three separate ANOVAs, with the normalized area measurements for the genu, splenium, and total corpus callosum area as dependent measures and diagnosis and gender serving as independent grouping factors. Criterion for significance was set at $P = .05$ for the ANOVA. Post hoc analyses of any significant main effects or interactions were conducted with the Student-Newman-Keuls procedure, with a criterion for significance set at $P = .05$. Spearman rank correlations were performed between the severity scores and the corpus callosum areas that showed significant main effects or interactions for diagnosis or hemisphere on the ANOVA. Because of multiple comparisons, the α value was set at $P<.01$ for these series of analyses.

RESULTS

Horizontal Area Measurements

Significant main effects for hemisphere ($F[1,45] = 8.83$, $P = .001$) and gender ($F[1,45] = 2.86$, $P = .02$) were obtained, and the diagnosis × hemisphere interaction was also significant ($F[1,45] = 2.49$, $P = .04$). Post hoc analysis of the hemispheric effects revealed that there were highly significant differences in the anterior polar 10% ($P = .001$), midanterior 20% ($P = .001$), and anterior central 20% ($P = .001$) segments, with the right side being larger than the left in these anterior segments. There was also a significant difference in the posterior polar 10% segment ($P = .004$), with the left side being larger than the right (Table 2) (Fig 3). Post hoc analysis of the gender effect revealed significant differences in the combined right and left areas of the midanterior 20% segment ($P = .003$) and the midposterior 20% segment ($P = .001$), where male subjects had larger area measurements than female subjects (Table 3), but there was no gender × hemisphere interaction. Finally, the diagnosis × hemisphere interaction post hoc analysis showed a significant effect only in the midposterior 20% segment ($P = .007$), where the right side of this segment was larger than the left in dyslexic readers, but the left side was slightly larger than the right in normal readers (Table 4). Spearman rank correlations revealed a significant positive correlation ($r = .58$, $P = .005$) between the severity score and the normalized area of the right side of the posterior polar 10% brain segment in dyslexic subjects.

Corpus Callosum Area Measurements

Results are summarized in Table 5 and Fig 4. Total corpus callosum measurement analysis revealed no ANOVA main effects for diagnosis or gender but did reveal a significant diagnosis × gender interaction (F[1,44] = 4.8, $P = .034$). Post hoc analysis revealed that dyslexic female subjects had a larger total corpus callosum area than dyslexic male or normal female subjects. In the genu measurements, there was also a diagnosis × gender interaction in the ANOVA analysis (F[1,44] = 5.12, $P = .029$). Post hoc analysis revealed that dyslexic female subjects had a larger genu area than dyslexic male subjects. Finally, in the splenium there were significant main effects for diagnosis (F[1,44] = 6.9, $P = .012$) (larger in dyslexic subjects) and for gender (F[1,44] = 8.65, $P = .005$) (larger in female subjects), but there was no significant diagnosis × gender effect. Post hoc analysis revealed that dyslexic female subjects had a larger splenial area than dyslexic male subjects, normal female subjects, and normal male subjects, but normal female subjects did not have a larger area than normal male subjects. Spearman rank correlations between severity scores and the relative sizes of the genu, splenium, and total corpus callosum were not significant in dyslexic subjects.

Table 2.—Normalized Horizontal Area Measurements* in All Subjects (Dyslexic and Normal Readers): Hemispheric Differences

COMMENT

Modern interest in the asymmetry of the human brain was stimulated by Geschwind and Levitsky[5] in their report that the length of the planum temporale measured in postmortem adult brains was asymmetrical and usually greater on the left side. A further report of asymmetry in the planum temporale, for both adult and infant human postmortem brains, was made by Wada et al,[29] and left-sided predominance was confirmed. In the frontal operculum, Wada et al found the right side to be larger than the left. LeMay and Kido[30] evaluated CT scans in right-handed subjects and reported left occipital petalia (indenting of the inner table of the skull) in about two thirds of their sample. While they found symmetry to be common in the frontal regions, 30% of their sample evidenced right frontal petalia and only 7% evidenced left frontal petalia. Other studies have confirmed these findings.[31-34]

Our results demonstrate that in quantitative area analyses of six bilateral brain regions, systematic asymmetry occurs in anterior and posterior brain regions. We have shown that the anterior three segments (corresponding to prefrontal, premotor, and insular cortex/superior temporal gyrus) are asymmetrical, with the right side being larger than the left, whereas in the posterior half of the brain, only the posterior polar 10% region, corresponding to the cuneus and lateral occipital lobe, is asymmetrical, with the left side being larger than the right. The region of the brain that includes most of the planum temporale, ie, the posterior central 20% segment, was found to be symmetrical in our study.

We were unable to find a gender difference in brain asymmetry, as described by Bear et al,[34] who reported a difference in degree of asymmetry with use of linear measurements in both frontal and occipital lobes, with female subjects exhibiting more symmetry than male subjects. The only gender differences we found were relative increases in male subjects in the size of the whole midanterior 20% region (encompassing the premotor region) and the midposterior 20% region (encompassing the angular gyrus). These differences between the findings of Bear et al[34] and our own may be related to the fact that we made area rather than linear measurements. Whether these anatomic differences are consistent and can be associated with

language or reading function will have to be determined in future studies.

Hier et al[16] studied 24 dyslexic subjects (two women, six "left-handed") with the use of CT of the brain. They observed that 10 dyslexic subjects had reversal of the usual left-greater-than-right asymmetry of posterior portions of the cerebral hemispheres; asymmetry was measured on a line drawn 5 mm anterior to the inner table of the skull at the occipital pole. These 10 subjects with reversed asymmetry had lower mean verbal IQ scores than the remaining 14 dyslexic subjects with either symmetrical posterior cerebral regions (six subjects) or the usual left-greater-than-right asymmetry (eight subjects). Haslam et al[18] evaluated brain CT scans in 26 right-handed boys (9 to 13 years of age) with developmental dyslexia and in eight right-handed boys, who were controls, using methods similar to those of Hier et al.[16] They found a lower-than-expected incidence of left-greater-than-right occipital asymmetry in the dyslexic group.

In our studies, the brain segment on the horizontal section that differentiated dyslexic and normal readers was midposterior 20%, which encompassed mainly the angular gyrus. The right side of this segment was found to be larger than the left in dyslexic subjects but symmetrical in nondyslexic subjects. It was also of interest that the region of the planum temporale, located within the posterior-central 20% segment, was not significantly different between dyslexic and nondyslexic subjects. The dyslexia severity score was found to correlate significantly with the area of the posterior polar 10% segment. This result indicated that the more severe the dyslexia, the larger the area of the right side of this segment.

Taken together, the above findings suggest that the major anatomic abnormality in dyslexic subjects is in two neighboring areas in the posterior part of the brain, encompassing mainly the angular gyrus and the posterior pole. This region tends to be larger than normal on the right side in dyslexic subjects. This finding is consistent with those of Hier et al[16] and Haslam et al,[18] even though these authors were unable to identify the brain regions that caused the differences between subject groups. It is these same structures that were found to be the most consistent sites of abnormality causing acquired alexia.[11,13]

In corpus callosum measurements, we found the splenium to be the region in this structure that showed the major findings of differences between genders and diagnostic groups. The splenium was larger in dyslexic female subjects than in dyslexic male subjects and larger in dyslexic than in normal readers. Little is currently known about the relationship between corpus callosum size and cognitive or functional abilities, although many theories abound. De Lacoste-Utamsing and Holloway[35] found the splenium of the corpus callosum to

Table 5.—Corpus Callosum Area Measurements* in Dyslexic and Normal Readers

*Values, unless otherwise noted, are mean ± SD. Value is expressed as a percentage of the midsagittal brain area.

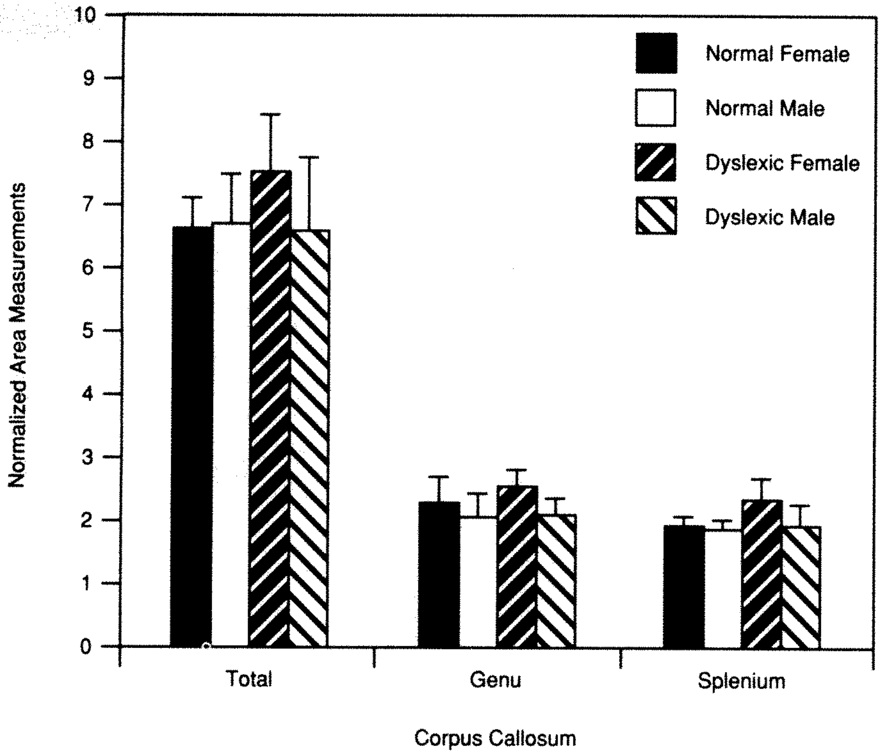

Fig 4.—Corpus callosum measurements (normalized to midsagittal brain area) in dyslexic and nondyslexic male and female subjects).

be larger in five female than in nine male subjects. They speculated that greater hemispheric specialization in male subjects, for visuospatial function, was linked to the smaller size of the male splenium. Although these gender differences in splenium size were not confirmed by Bleier et al[36] in 17 men and 22 women studied with MRI, these authors did not appear to have controlled for overall brain size. Witelson[37] evaluated the corpus callosum in 42 postmortem brains (12 male and 30 female; 27 consistent right-handers and 15 mixed-handers). She found that there was no sexual dimorphism in the size of the corpus callosum or any of its subdivisions but that mixed-handers had larger corpora callosa than consistent right-handers. This finding once again raised the issue of hemispheric specialization of function and corpus callosum size. Those with presumably less hemispheric specialization (mixed-handers) had larger corpora callosa. The size and shape of the corpus callosum appears to be at least partly under genetic control, as the variability of corpus callosum size is much less in monozygotic twin pairs than in randomly paired controls.[38]

With regard to gender differences in the size of the splenium, our results support those of De Lacoste-Utamsing and Holloway.[35] Our findings in dyslexic and normal subjects, however, are unique. The larger splenium that we found in dyslexic subjects would seem to fit well with the finding of an abnormality in the midposterior 20% segment in dyslexic subjects. Transcallosal pathways for the midposterior 20% region (angular gyrus) appear to be located in the splenium of the corpus callosum.[39] The basic assumption here is that reversed anatomic asymmetry in a brain region is associated with a greater degree of bihemispheric distribution of functions normally ascribed to that region. If this is correct, it may also suggest that the portion of the corpus callosum connecting the right and left halves of those brain regions will need to be larger to handle the greater amount of "cross-talk" required between these brain regions. No correlation was found, however, between the size of the splenium and the degree of asymmetry of the midposterior 20%, posterior central 20%, or posterior polar 10% segments ($r = .218$, $P = .10$; $r = -.05$, $P > .25$; $r = -.05$, $P > .25$, respectively). Thus, if there is a relationship between anatomic asymmetry of specific brain regions and the size of the corresponding segment of the corpus callosum, it is not a simple one. Nevertheless, the larger size of the splenium in dyslexic subjects does appear to add to the results obtained from horizontal section measurements. These results together suggest an anatomic abnormality in the posterior half of the brain.

In conclusion, we have shown that (1) the human brain is asymmetrical in the anterior half and the posterior pole; (2) male subjects have relatively larger brain segments than female subjects in a midfrontal and a midposterior location, representing the premotor and angular gyrus regions, respectively; (3) dyslexic subjects tend to have reversed brain asymmetry in a midposterior brain segment corresponding to the angular gyrus; (4) dyslexic subjects have a larger splenium of the corpus callosum than do normal readers; and (5) female dyslexic subjects have a larger splenium than do male dyslexic subjects. The functional importance of these findings will be better understood when correlated with markers of lateralized behaviors, as measured by psychophysical tests and neuropsychological tests, regional cerebral blood flow or metabolism, and brain electrical potentials.

This study was supported by grant 1-P01-HD21885-01A1 from the National Institute of Child Health and Human Development, Public Health Service, Bethesda, Md (entitled "Dyslexia Subtypes: Genetics, Behavior, and Brain Imaging").

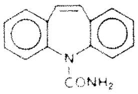
Before prescribing Tegretol, the physician should be thoroughly familiar with the details of this prescribing information, particularly regarding use with other drugs, especially those which accentuate toxicity potential.

DESCRIPTION

Tegretol carbamazepine USP is an anticonvulsant and specific analgesic for trigeminal neuralgia available as chewable tablets of 100 mg and tablets of 200 mg for oral administration Its chemical name is 5H-dibenz [b.f]azepine-5-carboxamide and its structural formula is



Carbamazepine USP is a white to off-white powder, practically insoluble in water and soluble in alcohol and in acetone Its molecular weight is 236 27

Inactive Ingredients Colloidal silicon dioxide FD&C Red No 3 (chewable tablets only). FD&C Red No 40 (200-mg tablets only). flavoring (chewable tablets only) gelatin. glycerin. magnesium stearate sodium starch glycolate (chewable tablets only). starch stearic acid and sucrose (chewable tablets only)

CLINICAL PHARMACOLOGY

In controlled clinical trials, Tegretol has been shown to be effective in the treatment of psychomotor and grand mal seizures, as well as trigeminal neuralgia

It has demonstrated anticonvulsant properties in rats and mice with electrically and chemically induced seizures It appears to act by reducing polysynaptic responses and blocking the posttetanic potentiation Tegretol greatly reduces or abolishes pain induced by stimulation of the infraorbital nerve in cats and rats It depresses thalamic potential and bulbar and polysynaptic reflexes, including the linguomandibular reflex in cats Tegretol is chemically unrelated to other anticonvulsants or other drugs used to control the pain of trigeminal neuralgia The mechanism of action remains unknown

Tegretol tablets are adequately absorbed after oral administration at a slower rate than a solution thus avoiding undesirably high peak concentrations Tegretol chewable tablets may produce higher peak levels than the same dose given as regular tablets Tegretol in blood is 76% bound to plasma proteins Plasma levels of Tegretol are variable and may range from 0 5-25 µg/ml, with no apparent relationship to the daily intake of the drug Usual adult therapeutic levels are between 4 and 12 µg/ml Following oral administration serum levels peak at 4 to 5 hours The CSF/serum ratio is 0 22 similar to the 22% unbound Tegretol in serum Because Tegretol may induce its own metabolism the half-life is also variable Initial half-life values range from 25-65 hours with 12-17 hours on repeated doses Tegretol is metabolized in the liver After oral administration of 14C-carbamazepine, 72% of the administered radioactivity was found in the urine and 28% in the feces This urinary radioactivity was composed largely of hydroxylated and conjugated metabolites with only 3% of unchanged Tegretol Transplacental passage of Tegretol is rapid (30 to 60 minutes), and the drug is accumulated in fetal tissues with higher levels found in liver and kidney than in brain and lungs

INDICATIONS AND USAGE

Epilepsy: Tegretol is indicated for use as an anticonvulsant drug Evidence supporting efficacy of Tegretol as an anticonvulsant was derived from active drug-controlled studies that enrolled patients with the following seizure types

1 Partial seizures with complex symptomatology (psychomotor temporal lobe) Patients with these seizures appear to show greater improvement than those with other types
2 Generalized tonic-clonic seizures (grand mal)
3 Mixed seizure patterns which include the above or other partial or generalized seizures

Absence seizures (petit mal) do not appear to be controlled by Tegretol (see PRECAUTIONS, General)

Trigeminal Neuralgia: Tegretol is indicated in the treatment of the pain associated with true trigeminal neuralgia

Beneficial results have also been reported in glossopharyngeal neuralgia

This drug is not a simple analgesic and should not be used for the relief of trivial aches or pains

CONTRAINDICATIONS

Tegretol should not be used in patients with a history of previous bone marrow depression hypersensitivity to the drug, or known sensitivity to any of the tricyclic compounds, such as amitriptyline desipramine, imipramine, protriptyline nortriptyline, etc Likewise, on theoretical grounds its use with monoamine oxidase inhibitors is not recommended Before administration of Tegretol, MAO inhibitors should be discontinued for a minimum of fourteen days or longer if the clinical situation permits

WARNINGS

Patients with a history of adverse hematologic reaction to any drug may be particularly at risk

Severe dermatologic reactions including toxic epidermal necrolysis (Lyell's syndrome) and Stevens-Johnson syndrome have been reported with Tegretol These reactions have been extremely rare However, a few fatalities have been reported

Tegretol has shown mild anticholinergic activity; therefore patients with increased intraocular pressure should be closely observed during therapy

Because of the relationship of the drug to other tricyclic compounds, the possibility of activation of a latent psychosis and, in elderly patients, of confusion or agitation should be borne in mind

PRECAUTIONS

General: Before initiating therapy, a detailed history and physical examination should be made

Tegretol should be used with caution in patients with a mixed seizure disorder that includes atypical absence seizures since in these patients Tegretol has been associated with increased frequency of generalized convulsions (see INDICATIONS AND USAGE)

Therapy should be prescribed only after critical benefit-to-risk appraisal in patients with a history of cardiac hepatic or renal damage adverse hematologic reaction to other drugs, or interrupted courses of therapy with Tegretol

Information for Patients: Patients should be made aware of the early toxic signs and symptoms of a potential hematologic problem, such as fever, sore throat, ulcers in the mouth easy bruising, petechial or purpuric hemorrhage, and should be advised to report to the physician immediately if any such signs or symptoms appear

Since dizziness and drowsiness may occur, patients should be cautioned about the hazards of operating machinery or automobiles or engaging in other potentially dangerous tasks

Laboratory Tests: Complete pretreatment blood counts, including platelets and possibly reticulocytes and serum iron, should be obtained as a baseline If a patient in the course of treatment exhibits low or decreased white blood cell or platelet counts, the patient should be monitored closely Discontinuation of the drug should be considered if any evidence of significant bone marrow depression develops

Baseline and periodic evaluations of liver function, particularly in patients with a history of liver disease must be performed during treatment with this drug since liver damage may occur The drug should be discontinued immediately in cases of aggravated liver dysfunction or active liver disease

Baseline and periodic eye examinations, including slit-lamp funduscopy and tonometry are recommended since many phenothiazines and related drugs have been shown to cause eye changes

Baseline and periodic complete urinalysis and BUN determinations are recommended for patients treated with this agent because of observed renal dysfunction

Monitoring of blood levels (see CLINICAL PHARMACOLOGY) has increased the efficacy and safety of anticonvulsants This monitoring may be particularly useful in cases of dramatic increase in seizure frequency and for verification of compliance In addition measurement of drug serum levels may aid in determining the cause of toxicity when more than one medication is being used

Thyroid function tests have been reported to show decreased values with Tegretol administered alone

Hyponatremia has been reported in association with Tegretol use, either alone or in combination with other drugs

Drug Interactions: The simultaneous administration of phenobarbital phenytoin or primidone or a combination of two produces a marked lowering of serum levels of Tegretol The effect of valproic acid on Tegretol blood levels is not clearly established although an increase in the ratio of active 10, 11-epoxide metabolite to parent compound is a consistent finding

The half-lives of phenytoin warfarin doxycycline and theophylline were significantly shortened when administered concurrently with Tegretol Haloperidol and valproic acid serum levels may be reduced when these drugs are administered with Tegretol The doses of these drugs may therefore have to be increased when Tegretol is added to the therapeutic regimen

Concomitant administration of Tegretol with erythromycin cimetidine, propoxyphene, isoniazid or calcium channel blockers has been reported to result in elevated plasma levels of carbamazepine resulting in toxicity in some cases Also concomitant administration of carbamazepine and lithium may increase the risk of neurotoxic side effects

Alterations of thyroid function have been reported in combination therapy with other anticonvulsant medications

Breakthrough bleeding has been reported among patients receiving concomitant oral contraceptives and their reliability may be adversely affected

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carbamazepine when administered to Sprague-Dawley rats for two years in the diet at doses of 25 75 and 250 mg/kg/day resulted in a dose-related increase in the incidence of hepatocellular tumors in females and of benign interstitial cell adenomas in the testes of males

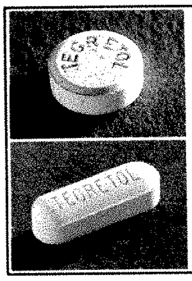
Carbamazepine must, therefore, be considered to be carcinogenic in Sprague-Dawley rats Bacterial and mammalian mutagenicity studies using carbamazepine produced negative results The significance of these findings relative to the use of carbamazepine in humans is at present unknown

Pregnancy Category C: Tegretol has been shown to have adverse effects in reproduction studies in rats when given orally in dosages 10-25 times the maximum human daily dosage of 1200 mg In rat teratology studies 2 of 135 offspring showed kinked ribs at 250 mg/kg and 4 of 119 offspring at 650 mg/kg showed other anomalies (cleft palate 1; talipes, 1, anophthalmos 2) In reproduction studies in rats nursing offspring demonstrated a lack of weight gain and an unkempt appearance at a maternal dosage level of 200 mg/kg

There are no adequate and well-controlled studies in pregnant women Epidemiological data suggest that there may be an association between the use of carbamazepine during pregnancy and congenital malformations including spina bifida Tegretol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus

Retrospective case reviews suggest that compared with monotherapy, there may be a higher prevalence of teratogenic effects associated with the use of anticonvulsants in combination therapy Therefore monotherapy is recommended for pregnant women

It is important to note that anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life In individual cases where the severity and frequency of the seizure disorder are such that removal of medication does not pose a serious threat to the patient discontinuation of the drug may be considered prior to and during pregnancy although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus



Only TEGRETOL,
brand of carbamazepine,
provides the prescribing
flexibility of a 100-mg scored
chewable tablet, as well as
a 200-mg scored tablet

Labor and Delivery: The effect of Tegretol on human labor and delivery is unknown

Nursing Mothers: During lactation concentration of Tegretol in milk is approximately 60% of the maternal plasma concentration

Because of the potential for serious adverse reactions in nursing infants from carbamazepine a decision should be made whether to discontinue nursing or to discontinue the drug taking into account the importance of the drug to the mother

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established

ADVERSE REACTIONS

If adverse reactions are of such severity that the drug must be discontinued the physician must be aware that abrupt discontinuation of any anticonvulsant drug in a responsive epileptic patient may lead to seizures or even status epilepticus with its life-threatening hazards

The most severe adverse reactions have been observed in the hemopoietic system (see boxed WARNING), the skin and the cardiovascular system

The most frequently observed adverse reactions, particularly during the initial phases of therapy are dizziness, drowsiness unsteadiness, nausea, and vomiting To minimize the possibility of such reactions therapy should be initiated at the low dosage recommended

The following additional adverse reactions have been reported

Hemopoietic System Aplastic anemia agranulocytosis pancytopenia bone marrow depression thrombocytopenia leukopenia, leukocytosis, eosinophilia acute intermittent porphyria

Skin Pruritic and erythematous rashes, urticaria toxic epidermal necrolysis (Lyell's syndrome) (see WARNINGS), Stevens-Johnson syndrome (see WARNINGS), photosensitivity reactions, alterations in skin pigmentation, exfoliative dermatitis erythema multiforme and nodosum, purpura aggravation of disseminated lupus erythematosus alopecia and diaphoresis in certain cases, discontinuation of therapy may be necessary

Cardiovascular System Congestive heart failure edema, aggravation of hypertension, hypotension syncope and collapse, aggravation of coronary artery disease arrhythmias and AV block primary thrombophlebitis recurrence of thrombophlebitis and adenopathy or lymphadenopathy

Some of these cardiovascular complications have resulted in fatalities Myocardial infarction has been associated with other tricyclic compounds

Liver Abnormalities in liver function tests cholestatic and hepatocellular jaundice, hepatitis

Respiratory System Pulmonary hypersensitivity characterized by fever dyspnea pneumonitis or pneumonia

Genitourinary System Urinary frequency acute urinary retention oliguria with elevated blood pressure, azotemia renal failure, and impotence Albuminuria glycosuria, elevated BUN and microscopic deposits in the urine have also been reported

Testicular atrophy occurred in rats receiving Tegretol orally from 4 to 52 weeks at dosage levels of 50 to 400 mg/kg/day Additionally rats receiving Tegretol in the diet for two years at dosage levels of 25 75, and 250 mg/kg/day had a dose-related incidence of testicular atrophy and aspermatogenesis In dogs it produced a brownish discoloration presumably a metabolite, in the urinary bladder at dosage levels of 50 mg/kg and higher Relevance of these findings to humans is unknown

Nervous System Dizziness drowsiness, disturbances of coordination, confusion, headache fatigue, blurred vision, visual hallucinations transient diplopia, oculomotor disturbances, nystagmus speech disturbances abnormal involuntary movements, peripheral neuritis and paresthesias, depression with agitation, talkativeness tinnitus, and hyperacusis

There have been reports of associated paralysis and other symptoms of cerebral arterial insufficiency, but the exact relationship of these reactions to the drug has not been established

Digestive System Nausea, vomiting, gastric distress and abdominal pain diarrhea, constipation anorexia and dryness of the mouth and pharynx including glossitis and stomatitis

Eyes Scattered, punctate, cortical lens opacities, as well as conjunctivitis have been reported Although a direct causal relationship has not been established many phenothiazines and related drugs have been shown to cause eye changes

Musculoskeletal System Aching joints and muscles, and leg cramps

Metabolism Fever and chills Inappropriate antidiuretic hormone (ADH) secretion syndrome has been reported Cases of frank water intoxication with decreased serum sodium (hyponatremia) and confusion have been reported in association with Tegretol use (see PRECAUTIONS, Laboratory Tests)

Other Isolated cases of a lupus erythematosus-like syndrome have been reported There have been occasional reports of elevated levels of cholesterol HDL cholesterol and triglycerides in patients taking anticonvulsants

A case of aseptic meningitis accompanied by myoclonus and peripheral eosinophilia has been reported in a patient taking carbamazepine in combination with other medications The patient was successfully dechallenged, and the meningitis reappeared upon rechallenge with carbamazepine

DRUG ABUSE AND DEPENDENCE

No evidence of abuse potential has been associated with Tegretol, nor is there evidence of psychological or physical dependence in humans

OVERDOSAGE

Acute Toxicity

Lowest known lethal dose adults >60 g (39-year-old man) Highest known doses survived adults 30 g (31-year-old woman), children 10 g (6-year-old boy), small children 5 g (3-year-old girl)

Oral LD 50 in animals (mg/kg) mice, 1100-3750; rats, 3850-4025, rabbits, 1500-2680, guinea pigs, 920

Signs and Symptoms

The first signs and symptoms appear after 1-3 hours Neuromuscular disturbances are the most prominent Cardiovascular disorders are generally milder and severe cardiac complications occur only when very high doses (>60 g) have been ingested

Respiration Irregular breathing, respiratory depression

Cardiovascular System Tachycardia, hypotension or hypertension, shock conduction disorders

Nervous System and Muscles Impairment of consciousness ranging in severity to deep coma Convulsions especially in small children Motor restlessness, muscular twitching tremor, athetoid movements opisthotonos, ataxia drowsiness, dizziness mydriasis nystagmus adiadochokinesia, ballism, psychomotor disturbances, dysmetria Initial hyperreflexia followed by hyporeflexia

Gastrointestinal Tract Nausea, vomiting

Kidneys and Bladder Anuria or oliguria, urinary retention

Laboratory Findings Isolated instances of overdosage have included leukocytosis reduced leukocyte count glycosuria and acetonuria EEG may show dysrhythmias

Combined Poisoning When alcohol, tricyclic antidepressants, barbiturates or hydantoins are taken at the same time the signs and symptoms of acute poisoning with Tegretol may be aggravated or modified

Treatment

The prognosis in cases of severe poisoning is critically dependent upon prompt elimination of the drug which may be achieved by inducing vomiting irrigating the stomach, and by taking appropriate steps to diminish absorption If these measures cannot be implemented without risk on the spot, the patient should be transferred at once to a hospital while ensuring that vital functions are safeguarded There is no specific antidote

Elimination of the Drug Induction of vomiting

Gastric lavage Even when more than 4 hours have elapsed following ingestion of the drug, the stomach should be repeatedly irrigated especially if the patient has also consumed alcohol

Measures to Reduce Absorption Activated charcoal laxatives

Measures to Accelerate Elimination Forced diuresis

Dialysis is indicated only in severe poisoning associated with renal failure Replacement transfusion is indicated in severe poisoning in small children

Respiratory Depression Keep the airways free; resort, if necessary, to endotracheal intubation artificial respiration, and administration of oxygen

Hypotension, Shock. Keep the patient's legs raised and administer a plasma expander If blood pressure fails to rise despite measures taken to increase plasma volume use of vasoactive substances should be considered

Convulsions Diazepam or barbiturates

Warning Diazepam or barbiturates may aggravate respiratory depression (especially in children), hypotension and coma However, barbiturates should not be used if drugs that inhibit monoamine oxidase have also been taken by the patient either in overdosage or in recent therapy (within one week)

Surveillance. Respiration, cardiac function (ECG monitoring), blood pressure body temperature pupillary reflexes and kidney and bladder function should be monitored for several days

Treatment of Blood Count Abnormalities If evidence of significant bone marrow depression develops the following recommendations are suggested (1) stop the drug (2) perform daily CBC, platelet and reticulocyte counts (3) do a bone marrow aspiration and trephine biopsy immediately and repeat with sufficient frequency to monitor recovery

Special periodic studies might be helpful as follows (1) white cell and platelet antibodies (2) 59Fe—ferrokinetic studies, (3) peripheral blood cell typing (4) cytogenetic studies on marrow and peripheral blood (5) bone marrow culture studies for colony-forming units (6) hemoglobin electrophoresis for A_2 and F hemoglobin and (7) serum folic acid and B_{12} levels

A fully developed aplastic anemia will require appropriate intensive monitoring and therapy, for which specialized consultation should be sought

DOSAGE AND ADMINISTRATION

Monitoring of blood levels has increased the efficacy and safety of anticonvulsants (see PRECAUTIONS, Laboratory Tests) Dosage should be adjusted to the needs of the individual patient A low initial daily dosage with a gradual increase is advised As soon as adequate control is achieved, the dosage may be reduced very gradually to the minimum effective level Tablets should be taken with meals

Epilepsy (see INDICATIONS AND USAGE)

Adults and children over 12 years of age—Initial: 200 mg b i d Increase at weekly intervals by adding up to 200 mg per day using a t i d or q i d regimen until the best response is obtained Dosage should generally not exceed 1000 mg daily in children 12 to 15 years of age and 1200 mg daily in patients above 15 years of age Doses up to 1600 mg daily have been used in adults in rare instances ***Maintenance:*** Adjust dosage to the minimum effective level, usually 800-1200 mg daily

Children 6-12 years of age—Initial: 100 mg b i d Increase at weekly intervals by adding 100 mg per day using a t i d or q i d regimen until the best response is obtained Dosage should generally not exceed 1000 mg ***Maintenance:*** Adjust dosage to the minimum effective level usually 400-800 mg daily

Combination Therapy: Tegretol may be used alone or with other anticonvulsants When added to existing anticonvulsant therapy, the drug should be added gradually while the other anticonvulsants are maintained or gradually decreased, except phenytoin which may have to be increased (see PRECAUTIONS, Drug Interactions and Pregnancy Category C)

Trigeminal Neuralgia (see INDICATIONS AND USAGE)

Initial: 100 mg b i d on the first day for a total daily dose of 200 mg This daily dose may be increased by up to 200 mg a day using increments of 100 mg every 12 hours only as needed to achieve freedom from pain Do not exceed 1200 mg daily

Maintenance: Control of pain can be maintained in most patients with 400 mg to 800 mg daily However, some patients may be maintained on as little as 200 mg daily while others may require as much as 1200 mg daily At least once every 3 months throughout the treatment period attempts should be made to reduce the dose to the minimum effective level or even to discontinue the drug

HOW SUPPLIED

Chewable Tablets 100 mg—round, red-speckled pink single-scored (imprinted Tegretol on one side and 52 twice on the scored side)

Bottles of 100	NDC 0028-0052-01
Unit Dose (blister pack)	
Box of 100 (strips of 10)	NDC 0028-0052-61

Tablets 200 mg—capsule-shaped, pink, single-scored (imprinted Tegretol on one side and 27 twice on the scored side)

Bottles of 100	NDC 0028-0027-01
Bottles of 1000	NDC 0028-0027-10
Gy-Pak*—One Unit	
12 bottles—100 tablets each	NDC 0028-0027-65

Magnetic Resonance Imaging White Matter Lesions and Cognitive Impairment in Hypertensive Individuals

Reinhold Schmidt, MD; Franz Fazekas, MD; Hans Offenbacher, MD; Helene Lytwyn, PhD; Brigitte Blematl, MD;
Kurt Niederkorn, MD; Susanna Horner, MD; Franz Payer, MD; Wolfgang Freidl, PhD

• To search for a morphologic basis of cognitive impairment possibly associated with essential hypertension, we studied 35 otherwise asymptomatic hypertensive individuals (mean age, 38.7 years; range, 22 to 49 years) and 20 normotensive control subjects (mean age, 37.9 years; range, 26 to 49 years) using neuropsychologic tests and magnetic resonance imaging. Irrespective of drug treatment, hypertensive individuals performed significantly worse than did control subjects when assessed for verbal memory and total learning and memory capacity, while there were no differences in test results of visual memory, attention, vigilance, and reaction time. The hypertensive individuals also described themselves as less active but ranked similar on five other mood subscales. Punctate high-signal intensities of the white matter were found almost twice as often in the hypertensive group (38%) as in the control group (20%). There was no difference in test performance between hypertensive individuals with and those without white matter lesions, however. Our results confirm the presence of subtle neuropsychologic deficits and indicate a higher frequency of white matter signal abnormalities in essential hypertension, as shown on magnetic resonance imaging, but do not indicate a correlation of these findings with each other.

(*Arch Neurol.* 1991;48:417-420)

Subtle deficits in the neuropsychologic test performance of hypertensive individuals appearing asymptomatic by standard clinical examination and interview have been reported by numerous groups.[1-6] The underlying mechanisms are still a matter of debate. "Functional" changes and/or parenchymal damage resulting from reduced cerebral perfusion have been implicated.[7-9]

The advent of magnetic resonance imaging (MRI) with its high sensitivity for tissue changes should provide the appropriate tool for testing the morphologic hypothesis.[10] So-called white matter lesions (WMLs) could represent the substrate looked for. These focal areas of high-signal intensity in the deep and subcortical white matter are an incidental finding on many MRI studies of both patients and neurologically asymptomatic individuals.[11-17] Hypertension is their main predictor besides age.[12]

Recently, Rao and coworkers[18] found no association between WML and neuropsychologic performance when examining healthy middle-aged volunteers. Subjects with hypertension were excluded from their study, however, and the authors concede that the cause and consequence of hyperintense white matter foci on MRI could be different for normotensive and hypertensive populations.

In the light of these results, we wanted to determine if hypertension-related tissue damage can be detected by MRI and cognitive impairment, if present in the group of hypertensive individuals, can be explained on the basis of these findings. To exclude other factors known to be associated with impaired cognitive performance and/or parenchymal abnormalities of the brain, we studied asymptomatic young and middle-aged individuals with essential arterial hypertension only.

SUBJECTS AND METHODS

Subjects

We studied 35 individuals (mean age, 38.7 ± 7.7 years; 26 men and nine women) suffering from essential hypertension. Attendants of a preventive medical examination program of the general regional health insurance company (Steiermärkische Gebietskrankenkasse, Graz, Austria) below 50 years of age who had had blood pressure readings greater than 160 mm Hg systolic and/or greater than 95 mm Hg diastolic at two independent visits or one reading above these limits and a history of hypertension were asked to participate in the study and were admitted to the Department of Neurology. Only those without clinical evidence of cardiovascular and/or cerebrovascular disease, diabetes mellitus, or other neurologic, psychiatric, or systemic disorders possibly associated with cognitive impairment or cerebral damage were then entered into the study. Subjects with a history of head injury and alcohol or drug abuse were not eligible for the same reasons.

In the study group the interval between the first diagnosis of hypertension and enrollment ranged from 1 to 139 months (mean, 74 months). Twenty-three subjects were treated with low-dose β-blockers (50-mg metoprolol, eight patients; 100-mg metoprolol, 10 patients; 50-mg atenolol, three patients; 100-mg celiprolol, one patient; and 5-mg carazolol, one patient). One patient received a combination of 0.4-mg dihydroergocristin mesylate, 2.5-mg clopamide, and 0.05-mg reserpine. Eleven individuals had not been taking medication for at least 1 month prior to the study.

The control group consisted of 20 volunteers (mean age, 37.9 ± 4.7 years; 13 men and seven women) from a field study on the incidence of cerebrovascular risk factors in Graz and the surrounding area, which was performed at the same time. They had to meet the same selection criteria as described for the hypertensive group, except for a negative history of hypertension and blood pressure recordings less than 140/85 mm Hg at two independent visits.

The demographic data of both groups and their blood pressure readings at the time of

The proton density magnetic resonance imaging sequence reveals multiple punctate hyperintense lesions in the deep and subcortical white matter of a 45-year-old hypertensive woman.

the MRI study are displayed in Table 1. All study subjects were right-handed.

Neuropsychologic Testing

We tested memory and learning abilities (Bäumler's Lern- und Gedächtnistest-LGT 3[19]), attention (d2 test[20]), vigilance and reaction time (computerized system by Quatember and Maly[21]), and mood (adjective list of Janke and Debus[22]). This battery was always administered in the same order and under the same laboratory conditions by one neuropsychologist unaware of the individual's diagnosis and MRI findings. All tests have been widely used for the assessment of normal populations in the German-language area.

Briefly, the Bäumler's Lern- und Gedächtnistest (LGT 3) is a highly demanding test for learning capacity and intermediate memory. It is a paper-pencil procedure and consists of six subtests. Three subtests (word and digit association tasks and story recall) assess verbal memory, and two subtests screen visuospatial memory (trail and design recall). The sum of weighted scores from these subtests and of an image recognition paradigm results in the total learning and memory performance score.

The d2 test is a letter identification test examining visual attention. The number of items correctly identified within 21 seconds per line is recorded. The distribution of errors among a total of 14 lines reflects attention span.

Vigilance and reaction time were determined with a computerized system developed by Quatember and Maly.[21] The individual is requested to identify changes in a sequence of light flashes, and the time needed for response is termed reaction time.

The test of Janke and Debus[22] is a self-administered questionnaire consisting of 136 adjectives describing states of activation, extro-introversion, well-being, emotional stress, and anxiety.

Magnetic Resonance Imaging

The MRI was performed with a 1.5-Tesla superconducting magnet (Gyroscan S 15, Philips, Eindhoven, the Netherlands) and the spin-echo technique. Sagittal T_1-weighted (TR/TE, 600/30 milliseconds) and axial proton density and T_2-weighted (TR/TE, 1800 to 2500/30 and 60 milliseconds) scans were obtained with a slice thickness of 5 mm. These images were reviewed for signal abnormalities and cerebral atrophy in a blinded fashion by randomly mixing the scans of control subjects and of 32 hypertensive patients (two patients were not scanned, and one set of images was excluded because of poor quality). Sulcal and ventricular enlargements were graded as not present, mild, moderate, or severe.

Statistical Analysis

Calculations were performed with the microcomputer version of the Statistical Package for Social Sciences.[23] One-way analysis of variance was employed first and the Duncan *t* test was used to ascertain significant differences between groups. Frequency distributions were compared by means of Fisher's Exact Test.

RESULTS

MRI Findings

Punctate hyperintense foci in the deep and subcortical white matter were the only signal abnormalities present on MRI scans of both groups (Figure). They were found almost twice as often in hypertensive patients as in control subjects (Table 2). The number of WMLs ranged from one to four (mean, 2.3) in normotensive individuals and from one to 19 (mean, 4.3) in hypertensive subjects. These differences did not reach statistical significance, however. Cortical and ventricular atrophies were found equally often in both groups (Table 2). The extent of atrophy was mild in most cases, except for one individual in each group with a moderate ventricular enlargement.

Neuropsychologic Testing

The hypertensive individuals performed worse than control subjects in almost all tests. Significant differences were reached with respect to the verbal memory and the total learning and memory scores ($P < .05$). This was true for both treated and untreated hypertensive subjects. An analysis for dose-dependent effects of the β-blocker most frequently used in our study group (metoprolol) revealed no significant differences in neuropsychologic performance of individuals on a 50-mg or 100-mg metoprolol regimen. Treated and untreated hypertensive subjects reported significantly lower degrees of activation (Table 3).

A comparison between hypertensive subjects with and without WML did not yield significantly different scores for any of the test items (Table 4). Analysis of potentially confounding factors in both groups revealed matching with respect to sex and length of education. Age was significantly higher in hypertensive subjects with WML (Table 4). The proportions of untreated patients (29% vs 35%) and of those receiving lipophilic (54% vs 60%) or hydrophilic (9% vs 5%) β-blockers in the samples with and without WML were comparable, with one patient with WML receiving a drug combination (8%).

COMMENT

In this study, clinically normal-appearing individuals below 50 years of age with essential arterial hypertension obtained significantly lower scores than normotensive control subjects for overall memory performance and learning capacity and on subscales assessing verbal mnemonic abilities. Our data, thus, confirm that neuropsychologic testing may reveal unexpected cognitive impairment in such hypertensive populations.[4-6]

Several reports indicate either improvement or impairment of cognitive performance from β-blockers.[24] The differences in test results observed between normotensive and hypertensive subjects in this study, however, cannot be explained on the basis of drug effects. Hypertensive subjects with and

without medication performed equally poorly. Moreover, a major drug influence is unlikely as dosages of β-blockers in our patients were in the low range, while cognitive alterations have been noted rather with high-dose regimens. The proportion of patients receiving lipophilic β-blockers, predominantly incriminated for cognitive side effects because of their brain affinity, was small compared with that of hypertensive subjects treated with substances of the hydrophilic type. Dose dependency of neuropsychologic impairment was not noted in the most frequently used representative of the latter. A comparable length of education in hypertensive patients and control subjects excludes a distortion of our finding by this factor as well.[6]

The mood questionnaire revealed significantly lower levels of activation for hypertensive individuals than for control subjects. A negative effect on mood state and personality from the recognition of worse cognitive performance has been suggested by Shapiro et al.[25] Conversely, a reduced state of activation as present in our hypertensive patients could deteriorate test performance and might have affected cognitive testing.

To our knowledge, it is the first time that MRI was used to look for a morphologic basis of subtle neuropsychologic alterations in otherwise asymptomatic hypertensive individuals. Punctate high-signal intensity lesions in the deep and subcortical white matter were noted in more than one third of this population, and this was almost twice as often as in normotensive control subjects. Recent histopathological studies indicate atrophic perivascular demyelination and gliosis resulting from focally insufficient nutrition around small vessels[26] and/or frank lacunar white matter infarcts[27,28] as the predominant correlate of such signal abnormalities. They could, thus, be a first step toward hypertensive subcortical arteriosclerotic encephalopathy, which is frequently associated with dementia.[29] The comparison of hypertensive subjects with and without WML did not reveal a significant difference on any of the administered neuropsychologic tests, however. A mismatch of both groups with respect to sex, length of education, or type of treatment that might have caused a false-negative finding could not be substantiated. Age was significantly higher in the group of hypertensive subjects with WML. This is not unexpected as Awad et al[12] identified both age and hypertension as the most important predictors of incidental MRI hyperintensities. With respect to cognitive testing, however, the higher mean age of hypertensive subjects with WML should have rather enhanced a worse performance than masked it.

It, therefore, appears that the type of MRI lesions observed in this study cannot be implicated in the cognitive impairment noted. Moreover, white matter changes described in MRI of vascular dementia and seen in cases with pathologically proved Binswanger's disease have been reported as more extensive, sometimes involving almost the entire periventricular and deep white matter.[14,29,30]

As the frequency of atrophy was also not different between normotensive and hypertensive subjects, MRI could not provide an explanation for our neuropsychologic observations. Therefore, these data are in favor of "functional" or at least not gross structural mechanisms that deteriorate cognitive performance in hypertensives of this age group.

Visual Art in the Neurologic Career of Jean-Martin Charcot

Christopher G. Goetz, MD

• Jean-Martin Charcot, the world's first chaired professor of neurology, incorporated visual art into his daily practice of neurology. Art served as scientific documentation and was a pivotal tool in the development and dissemination of Charcot's clinicoanatomic method. Although Charcot drew extensively in clinical and laboratory studies, very few of these visual documents have ever been published or are currently available for public study. Charcot was central to the incorporation of medical photographs into the study of neurologic disease and relied heavily on visual material in his capacity as an international teacher. Art also misguided Charcot's career when he relied heavily on artwork in his attempt to convince critics that disorders seen at the Salpêtrière Hospital, Paris, France, were independent of his suggestive influence.

(*Arch Neurol.* 1991;48:421-425)

As a physician at the Salpêtrière Hospital, Paris, France, and the world's first chaired professor of neurology, Jean-Martin Charcot considered art and science to be pivotally complementary in his effort to describe and categorize neurologic disease. Science nourished art as Charcot used his own patients as models in his neurologic sketches and photographs; art nourished neurology as Charcot used art objects from past ages to convince critics that certain of the disorders he sometimes described were neither new nor of his own creation. Charcot's incorporation of art into neurology guided and misguided his individual career and established a visual tradition in neurologic study that persists today, although in new technologic forms.

ART AS SCIENTIFIC DOCUMENTATION

Charcot's dual devotion to art and science was reportedly lifelong, and he had wrestled between medicine and art as careers.[1] Charcot finally chose medicine and enrolled in the national medical school in Paris in 1842. There is almost no documentation of his student years, and his first known medical drawings date from when Charcot came to the Salpêtrière as a junior faculty member. Almost none of Charcot's clinical drawings have ever been published, and they are not available for public viewing.

After arriving at the Salpêtrière, Charcot's first task was to examine and categorize the thousands of patients haphazardly housed together throughout the walled hospital village of the Salpêtrière. With his colleague, Vulpian, Charcot gathered a massive clinical database of neurologic and geriatric diseases. This material became the core of Charcot's clinicoanatomic method, the hallmark of his Salpêtrière school.[2]

The two-step clinicoanatomic method involved artistic documentation in both phases. The first step focused on clinical description of neurologic disease, and Charcot's patient drawings documented the static deformities of chronic cases as well as evolving signs of acute illnesses. Whereas the notes accompanying the drawings were often long-winded, the drawings rapidly communicated a patient's changing neurologic state (Fig 1). Using art, Charcot documented unusual cases of dramatic amputees, pockmarked victims, and contracted hemiplegics as well as more typical cases of vascular and neurodegenerative diseases (Fig 2).

The second step of the clinicoanatomic method, which focused on anatomic and microscopic analyses, occurred after the patient died. Here, too, Charcot used his artistic skills and later engaged professional artists. He traced lesions throughout the neuraxis and documented vascular anomalies in detail (Fig 3). His early drawings were among the first to document the microscopic changes of multiple sclerosis and the spinal changes of amyotrophic lateral sclerosis (Fig 4).

Charcot's self-appointed charge was to be an objective observer, articulate and clear, independent of preconceived prejudice or expectation.[3] His personal artistic preferences focused primarily on the Dutch masters, whose realism revealed the world with simplicity and unadorned clarity.[4] His own personal artistic style reflected his scientific approach to clinical neurology. His most distinguishing clinical characteristic was a keen ability to see the essential features of diseases, culling them from among the confusion of detail. He likewise sketched with an economy of line that permitted viewers to grasp essential features at a glance. Whereas his artworks showed little artistic refinement, they were effective documents of immediate visual impact. He drew patients wherever he

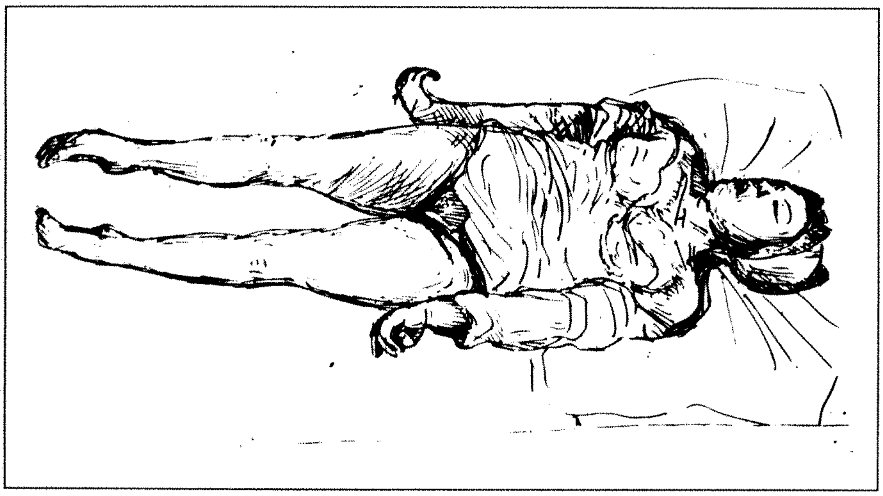

Fig 2.—Patient with decerebrate rigidity (original drawing in Bibliothèque Charcot, Salpêtrière Hospital, Paris, France).

saw them, and even when he was on vacation or on foreign travel, neurologic disease did not escape his eyes. For example, he sketched a North African with Parkinson's disease, capturing in his hasty strokes the hand posture, body attitude, joint deformities, and masked facies typical of the disease (Fig 5).

CHARCOT AND PHOTOGRAPHY

Charcot's artistic interests were undoubtedly at the core of his immediate appreciation of the new art of photography. Under his direction, a photographic service at the Salpêtrière was established by Londe,[5] and patients were regularly photographed as part of their neurologic evaluation. Whereas those with static findings were photographed only once or twice at different angles, the photographers became increasingly adept at documenting dynamic disorders with sequential and time-lapse photography methods (Fig 6). Charcot even spoke of himself in photographic terms: "I only observe, nothing more," and "I am a photographer."[6]

The Salpêtrière photographs were printed on positive silver plates, and several thousands of them were generated during Charcot's career. Some of these and many more from the period after Charcot's death are today housed in the Countway Medical Library, Boston, Mass. Such pictorial documents formed the foundation of two of Charcot's major neurologic enterprises, the *Iconographie Photographique* and the *Nouvelle Iconographie de la Salpêtrière*. The former was a limited edition of hand-pasted photographs documenting the various disorders, primarily epilepsy and hysteria, seen in the Charcot service. The latter replaced this set with a larger circulation journal with neurologic articles based specifically on photographic or artistic documentation. In the introduction of the first volume of the *Nouvelle Iconographie de la Salpêtrière*, the editors wrote:

> When a patient demonstrates signs of particular interest—various atrophies, contractures, special postures or deformities—he is immediately drawn or photographed. With the aid of this immediate record, we are able to freeze the abnormality, to decompose the various abnormal movements one by one, and thereby capture the disorder with precision. These vignettes from the Salpêtrière complement the clinical examination to form a collection of great significance.[7]

Contemporary journals based on photography or videotape (eg, *Movement Disorders*) are modern descendants of this Charcot tradition.

ART AND TEACHING

The incorporation of an artistic effort in the Charcot service had important consequences not directly linked to scientific documentation. Visual material, by nature, extends beyond language barriers and bypasses technical medical terminology. It can attract attention and provoke inquiry that might be passed over in a dry account of written neurologic description. When Charcot started his faculty career, he was acutely aware that the Salpêtrière was considered far from central Paris and that it carried the stigma of an academic wasteland, "an exile in a lost land where the pathologists and clinician had very little to see."[8] To attract students, Charcot compiled a series of rehearsed-to-perfection lessons on selected medical topics. He incorporated all his resources in these efforts, and each year their appeal grew wider. His drawings, charts, and theoretical constructs were presented in multicolored spectacle. Fifteen years before the better known aphasia diagrams of Lichteim were created, Charcot presented his audience with an elaborate series of drawings involving a bell as the central theme (Fig 7). Charcot was among the first teachers to use slide projec-

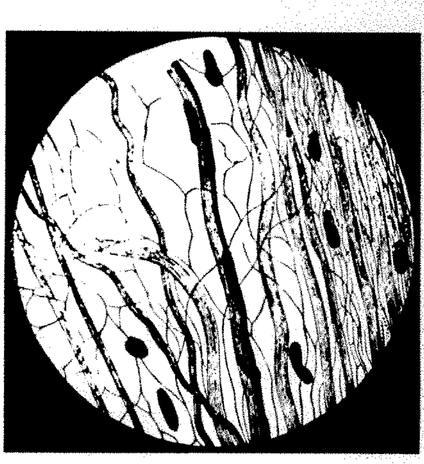

Fig 4.—Denuded axons and maintained neurons in multiple sclerosis. Drawn by Charcot and published in his *Oeuvres Complètes*.

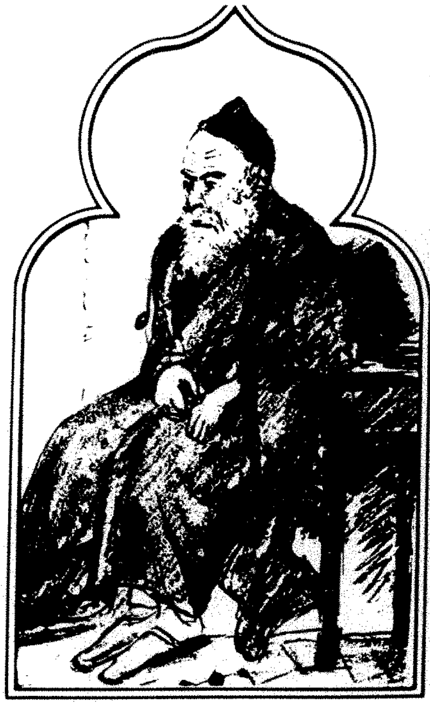

Fig 5.—A drawing by Charcot of a Moroccan with Parkinson's disease (1889). "I have seen such patients everywhere, in Rome, Amsterdam, Spain, always the same picture."[3]

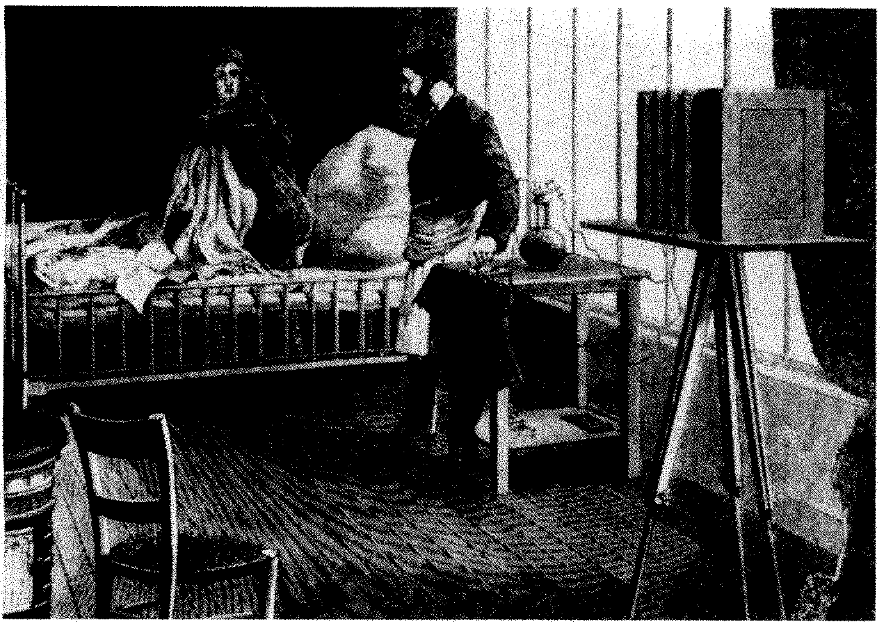

Fig 6.—Londe[5] photographing a patient in her room at the Salpêtrière Hospital, Paris, France. The photographic service was a regular part of the neurologic evaluation and research effort under Charcot's direction (from *La Nature*, No. 536; Paris, France: Bureaux du Progrès Médical; 1892.

tors in his classroom. He brought statues, photographs, and patients themselves as visual documents. He also was an excellent mime and recreated clinical syndromes for his audience, including gait abnormalities, parkinsonism, tic disorders, and various types of weakness.[2]

Charcot's reputation of magnetic presentations extended beyond the Paris medical system to the foreign medical world and to nonmedical Paris society. Especially in the 1880s and in his last years, Charcot's classroom was a mélange of doctors from eastern and western Europe and the Americas, as well as Parisian artists, journalists, politicians, and social commentators. For many of these people, whose familiarity with French or with medicine was weak, the visual material was undoubtedly pivotal to effective communication. As the American Alan Starr recalled when he first saw Charcot in a classroom:

> But grant that it was theatrical; it left on the mind of the student a series of mental pictures of patients and of lessons which no amount of private study could possibly produce. It taught man so that they could not fail to remember; and what higher result can a teacher wish?[9]

Clearly Charcot was not the first or the only investigator to use medical illustration and visual arts as a means of medical documentation. His con-

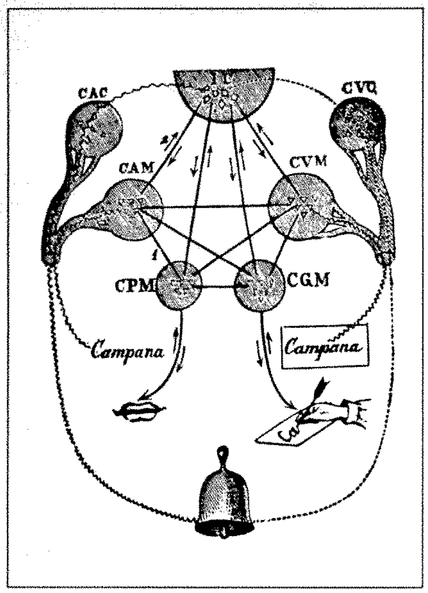

Fig 7.—Diagram of a bell used by Charcot in his presentations on aphasia. IC indicates center for ideas; CAC, auditory center; CVC, visual center; CAM, auditory center for words; CVM, visual center for words; CPM, phonetic center for words; and CGM, graphic center for words.[17]

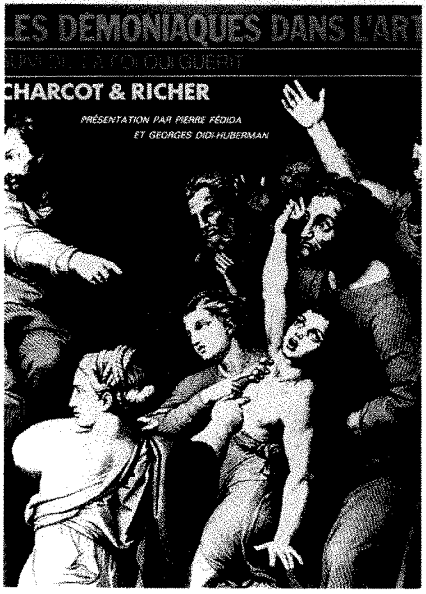

Fig 8.—Cover from Charcot's and Richer's *Demonics in Art,* showing one of the drawings used by the authors to support their thesis that hysterical epileptic fits were not a new disorder nor were they behaviors found only, or predominantly, at the Salpêtrière Hospital, Paris, France.

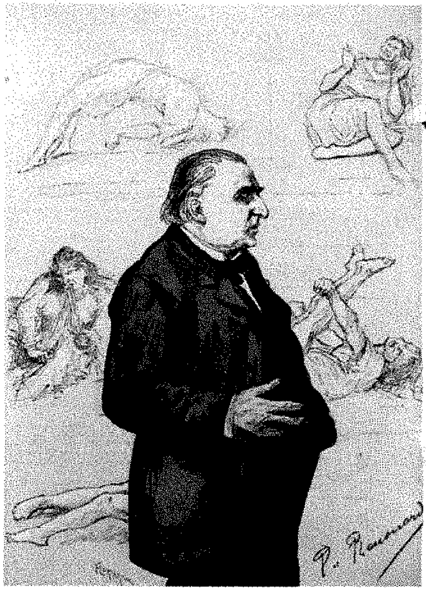

Fig 10.—Charcot and his patients. This picture was on the cover of the Paris tabloid *Revue Illustrée* and shows the extent to which Charcot became a popularized figure in nonmedical society (from Countway Medical Library, Harvard University, Boston, Mass).

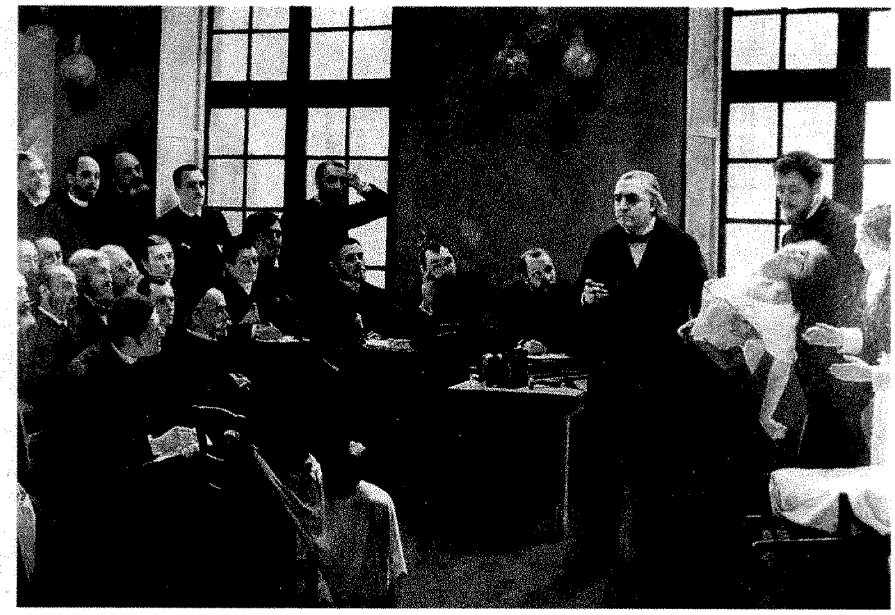

Fig 9.—A clinical lesson at the Salpêtrière Hospital, Paris, France, by Brouillet, prepared for the 1887 Paris Salon and showing Charcot, Babinski, Marie, Tourette, and other physicians, as well as artists, social commentators, and government officials in attendance.

temporaries Gowers and Hughlings Jackson included their own medical drawings in their text. Charcot, however, used visual arts in every aspect of his daily work effort. Art at the Salpêtrière was inseparable from the scientific effort and was as much the embodiment of the clinicoanatomic method as any other neurologic activity under Charcot's direction.

ART AS SCIENTIFIC JUSTIFICATION

In the sphere of organic neurology, Charcot's clinicoanatomic method met with repeated successes and established him and his school as the international pillars of clinical neurology. In the 1870s and thereafter, however, he increasingly devoted his attention to hysteria, a topic that had haunted and befuddled physicians before him.[10,11] In working with hysteria and attempting to apply the clinicoanatomic method to a condition with an elusive lesion, Charcot drifted in the eyes of his contemporaries. Visiting physicians did not recognize the spells he demonstrated in the amphitheater of the Salpêtrière, and, because the spells were too dramatic to be missed if they actually existed elsewhere, critics contended that they must be feigned or created by Charcot's own powerful suggestion. Charcot was keenly aware that hysteroepilepsy became derisively known as the Salpêtrière illness.[6]

To address this criticism and rescue his compromised scientific reputation, Charcot called on art in a way he had never previously used it. While lecturing to his students that hysteria "must henceforth become a household word,"[12] he looked to art to demonstrate that the behaviors he saw were independent of him. He went outside the Salpêtrière, beyond medicine, and indeed out of the time constraints of his own era to justify his stand that the signs of hysteria were implicit to the disease and not to the observer. At a time when he relegated much of his publication material to students, he embarked on two major works on neurologic disease in art, *The Disease and Deformed in Art* and *The Demonics in Art,* both largely focusing on hysteria (Fig 8). These works were pointedly aimed at repudiating suspicions of manipulation of falsification of clinical medicine.

In them, Charcot demonstrated that behaviors similar to those seen at the Salpêtrière could be found in medieval and mannerist paintings and other artworks depicting demonic possession or spiritual ecstacy. Charcot, however, did not succeed in accomplishing his goal, and he did not convince scientific skeptics that his personality was not intimately connected to the behaviors seen at the Salpêtrière.[13] In fact, Charcot's mere reliance on religious art that was doubtfully conceived or executed with objectivity as its guiding force and the glaring lack of historical or genre painting to support his thesis suggest a certain intellectual desperation in a man otherwise so perceptually acute. In the end, Charcot apparently recognized that his efforts had failed. The last night he worked on scientific material before he died, he reportedly told Guinon[14]: "Our conception of hysteria has become obsolete. A total revamping of this area of neurologic disease is required."

ART AS SOCIAL VEHICLE

In spite of his failure to justify scientific credibility through art, Charcot's artistic projects were of significant personal and social benefit. With them, he effectively presented himself as a multitalented and culturally sophisticated man. The importance of this dimension to his career should not be underestimated, for Charcot came from very humble origins. If a certain underlying cultural insecurity existed, his extensive literary references to poetry and Shakespeare and his artistic allusions that spanned the centuries of western culture obviously helped Charcot to present himself as a man of Renaissance dimension.[2,15] He also posed as the focal point for an immense group portrait by Brouillet, "A Clinical Lesson at the Salpêtrière" (Fig 9), a painting that became part of the celebrated 1887 Paris Salon, the focal point of artistic Paris at the time.[16] His name was known to the public, and he was even pictured on the cover of a popular street tabloid surrounded by his patients (Fig 10). These documents demonstrate that by the close of his career, Charcot, the Salpêtrière, and neurology had entered into the current social consciousness of the time. In these ways, art served Charcot directly to broaden his image and to solidify him as a cultural as well as a scientific figure of French society in the glittering close of the 19th century. Without this dimension and the close political ties that Charcot cultivated with Gambetta and other governmental figures of the third French Republic, one could question whether the original chair of neurologic diseases would ever have been established as early as 1882, and specifically in Paris at the Salpêtrière.

CHARCOT'S NEUROLOGIC ARTISTIC LEGACY

In 1893, when Charcot died, the Salpêtrière service included artists, sculptors, photographers, and a team of young neurologists well versed in visual documentation. Thereafter, the photographic wing actively continued for several generations, and the *Nouvelle Iconographie de la Salpêtrière* was published until 1929. In the 1950s, however, the Charcot Museum, with its extensive documentation of the Salpêtrière visual effort, was dissolved and the collection was lost or dispersed.[2] A pivotal investment in visual medical documentation is no longer specifically linked to the Salpêtrière, nor has it been for the past 70 years, and more recent international generations have developed innovative applications of scanning devices, videotaping, and other technologies that continue Charcot's tradition of visual neurologic documentation. These techniques are pivotal to the continued application of the clinicoanatomic neurologic method and to the refinement of modern neurologic nosology. As the centenary of Charcot's death approaches and the neurologic world invests increasingly in reexamining his written legacy, the "visual Charcot" deserves emphasis because it coalesces neurologist, teacher, social figure, and private citizen without needed grammatical translation or language study.

1991
International Conference on Physician Health

June 6-8, 1991
Toronto, Ontario, Canada

Sponsored by
American Medical Association
Canadian Medical Association
Federation of Medical Licensing Authorities of Canada

This year's conference, *Caring for the Caregiver*, will address a range of issues relative to physician health, including aging, physical disabilities, psychiatric disorders, and substance abuse. Through the presentation of scientific data and the provision of training workshops, this conference will offer an overview of the current status of the field as well as educational opportunities for the conference participants.

Please join the AMA, CMA, and Federation for this exciting and innovative conference, which:

- Gives participants an opportunity to hear of the latest developments in this important field
- Provides opportunity to learn skills necessary for conducting research in various areas of physician health
- Examines the differing treatment programs and their relative values
- Offers these important features–
    - State-of-the-art research presentations
    - Invited speakers
    - Selected workshops
    - Pre-conference institutes
    - Extensive networking opportunities
    - Exhibits

For more information regarding registration call **toll-free 1-800-621-8335.** For event sponsorship, or invitation to exhibit call Patrick W. McGuffin, PhD, at 1-312-464-4064.

Observations

Internal Capsule Plaque and Tonic Spasms in Multiple Sclerosis

Davide Maimone, MD; Anthony T. Reder, MD; Francesco Finocchiaro, MD; Egidio Recupero, MD

• A patient developed hemilateral tonic spasms associated with a relapse of multiple sclerosis. An area of demyelination in the right internal capsule was observed on a magnetic resonance imaging scan. This lesion was not detectable on a second magnetic resonance imaging scan 10 months after the spasms had ceased. Paroxysmal symptoms in multiple sclerosis may represent transient phenomena related to inflammation in acute plaques.

(*Arch Neurol.* 1991;48:427-429)

Paroxysmal symptoms in multiple sclerosis (MS) include trigeminal neuralgia; dysarthria; ataxia; tonic spasms, or "paroxysmal dystonia"; akinesia; and painful paresthesias.[1] These transient disturbances are sometimes the initial manifestation of the disease and usually disappear after several weeks.[2]

It has been postulated that the causative lesions are strategically localized in the spinal cord or brain stem.[3,4] However, plaques in the contralateral hemispheric white matter can also be associated with tonic spasms.[5,6]

We describe a young woman with definite MS[7] who developed unilateral tonic spasms associated with a plaque in the contralateral internal capsule. After the attacks resolved, the lesion was no longer evident on magnetic resonance imaging (MRI) scan, showing that tonic spasms in MS may result from plaques located above the brain stem. Paroxysmal symptoms in MS are more likely to occur during active demyelination and may be secondary to axonal irritation by lymphokines.

REPORT OF A CASE

A 26-year-old woman was admitted with a 10-day history of tonic spasms. These were characterized by tonic flexion of the left elbow and wrist and extension of the fingers at the metacarpophalangeal and proximal interphalangeal joints. The left leg was extended with plantar flexion and moderate intrarotation of the foot. Left facial grimacing was often present, as well as a sense of painful discomfort. These spasms were not associated with aura, loss of consciousness, tonic clonic movements, loss of sphincter control, or postictal phenomena. The attacks were mostly spontaneous, lasted 15 to 30 seconds, and occurred 20 to 30 times a day. They could be occasionally elicited by sustained extension of the arms or by sudden emotions.

Three weeks earlier, the patient had experienced dizziness and mild left hemiparesis, with ipsilateral numbness and paresthesias. The diagnosis was possible MS, and the patient was treated with cosyntropin. After 7 days she was discharged in remission, but developed the paroxysms 7 days later.

On admission, she had a mild left hemiparesis and left central facial paresis, right internuclear ophthalmoplegia, and slight impairment of vibratory sensation in the left limbs. Her left knee reflex was moderately brisk and left abdominal reflexes were absent, but plantar responses were normal on both sides. Carbamazepine, 200 mg twice a day, aborted the crises in 2 days.

The complete blood cell count, erythrocyte sedimentation rate, blood chemistry values, antinuclear antibody titer, complement levels, and serum immunoglobulin values were normal. The cerebrospinal fluid had seven nucleated cells per cubic millimeter, an elevated IgG index (0.97; normal, <0.7), increased intrathecal IgG synthesis rate (6.7 mg/d; normal, <3.3 mg/d), and oligoclonal bands.

Repeated electroencephalographic recordings during the attacks and interictally were normal. The visual evoked potentials, brain-stem auditory evoked potentials, and somatosensory evoked potentials were within normal ranges. The computed tomographic scan did not show any low-density or enhancing white matter lesions or other focal lesions.

The MRI study was performed on a 0.5-T system. On T_2-weighted images, an area of increased signal was located in the posterior limb of the right internal capsule (Fig 1).

Ten months later, the patient experienced a new episode of right-sided weakness and tingling and unsteadiness of gait. She had a mild right hemiparesis with brisk deep tendon reflexes bilaterally, a right extensor plantar response, horizontal nystagmus, and decreased vibratory sensation in the distal lower limbs. No abnormal movements or other paroxysmal symptoms occurred.

On MRI, new foci of increased T_2 signal appeared in the periventricular white matter and the left internal capsule (Fig 2). The previous lesion in the internal capsule of the right hemisphere was no longer evident.

Another cosyntropin treatment was given, and the patient was discharged in remission after 2 weeks of therapy.

COMMENT

Tonic spasms, also known as tonic seizures or paroxysmal dystonia, are sudden attacks of abnormal involuntary postures of one or more limbs, and often resemble tetanic spasms.[8] They can be associated with facial grimacing and painful sensations that localize to the same areas as the motor symptoms. Their distribution is

mainly unilateral, although contralateral spreading and bilateral attacks have also been reported.[4,9] Autonomic symptoms may occur, and include piloerection, perspiration, and skin flushing.[4,9] Tonic spasms are usually spontaneous, but can be evoked by active or passive movements,[4,8,10] sensory stimuli,[4,8,10] hyperventilation,[4,10,11] or emotions. The spasms last for only 30 seconds to 2 minutes, but they occur at high frequencies, ranging from 10 to 30 times a day. Almost invariably the spasms subside after weeks or months without treatment. Some antiepileptic drugs (eg, carbamazepine) suppress the attacks within a few days.[11]

Although tonic spasms may occur in various neurologic disorders,[12] they are most commonly associated with MS. Before computerized imaging techniques, it was postulated that tonic spasms were caused by MS plaques in the brain stem or the spinal cord.[5,6] More recently, hemilateral tonic spasms in two patients with MS were associated with lesions in the contralateral internal capsule on computed tomographic or MRI scans.[3,4] In our patient, the association of left-sided tonic spasms with a plaque in the right internal capsule seems more than fortuitous. The internal capsule lesion was the sole area of demyelination detected on MRI when the paroxysms occurred. Furthermore, the solitary plaque was located above the brain stem, providing an anatomical explanation for the clinical signs of contralateral spasms and facial grimacing.

Paroxysmal symptoms in MS, particularly tonic spasms, have been proposed to have an epileptic origin[8,10] because of their therapeutic response to antiepileptic drugs and their similarity to some forms of reflex epilepsy. A cortical localization, however, appears unlikely because there is no alteration of consciousness, even when tonic spasms spread bilaterally, and because there is a total lack of paroxysmal activity on the electroencephalogram. For these reasons, tonic spasms would be more likely to originate at subcortical, mesencephalic, or spinal levels.[3,4,8-10]

Demyelination causes axons to be hypersensitive to minor insults.[11] Paroxysms could then be triggered by reduction of ionized calcium after hyperventilation[8] or by ephaptic activation of axons in plaques.[1] Demyelination of afferent inhibitory pathways might also contribute to the pathologic discharges.[1]

In addition, inflammatory irritation could provoke paroxysmal symptoms.[9] Active lesions in MS are characterized by lymphocytic infiltrates and in situ secretion of lymphokines and interferons.[13,14] Leukocyte interferon and interleukin 2 enhance excitability of neurons.[15-17] Soluble factors released during inflammation could excite demyelinated axons in MS plaques.

In our case, as in most reported cases, the paroxysms were associated with other signs of exacerbation. The disappearance of the MRI lesion corresponded with the remission of symptoms. Changes in MRI plaques can develop over time in relapsing-remitting MS and tend to parallel the clinical activity of the disease.[18,19] The reported duration of several weeks for these transient plaques is temporally consistent with the natural course of paroxysms in MS.[2,19] Hyperactivity of the immune system occurs during MS exacerbations,[20,21] and inflammatory infiltrates are found in active plaques.[22] We suggest that paroxysmal symptoms in MS may sometimes originate from axonal irritation secondary to release of excitatory lymphokines.

This study was supported in part by a grant from Progetto di ricerca finalizzata 27/M, Assessorato alla Sanità, Regione Sicilia.

Hypothalamic or Central Obesity Is Associated With an Early Rise in Plasma Insulin Concentration

Michael M. Segal, MD, PhD; Jennifer Bell, MD; Gary M. Abrams, MD

• Insulin levels in a 7-year-old boy with hyperphagia and obesity following an episode of meningoencephalitis were studied sequentially during the course of progressive weight gain. High fasting insulin levels (1183 pmol/L) and strikingly high insulin release in response to glucose (7892 pmol/L) were found within weeks of the onset of the illness. The abnormality in insulin secretion occurred prior to the marked weight gain. Hyperinsulinemia was not accompanied by hypoglycemia. Early hyperinsulinemia may be a primary event in the development of hyperphagia and obesity following hypothalamic injury.

The metabolic basis of weight gain in patients with hypothalamic obesity is incompletely understood because of the rarity of hypothalamic obesity and the lack of clinical investigative studies concerning the early stage of the illness. Hyperinsulinemia has previously been found in humans studied years after the onset of hypothalamic obesity. However, in most respects, patients with hypothalamic obesity show a similar pattern of carbohydrate tolerance and insulin secretion to that in patients with exogenous obesity.[1]

In experimental animals, ventromedial hypothalamic lesions induce a syndrome characterized by hyperphagia and obesity.[2] An analogous syndrome has been described in humans with pathologic processes that involve the basal medial hypothalamus.[3,4] Hyperphagia and obesity in the rats with ventromedial hypothalamic lesions are accompanied by an early rise in plasma insulin levels, prior to the onset of hyperphagia or obesity.[5] The hyperinsulinemia appears to be mediated by a direct action of vagal axons on beta cells in the pancreas.[6,7] Although it is unsettled whether hyperinsulinemia is the cause of the hyperphagia and obesity in the animal with a ventromedial hypothalamic lesion, the role of the central nervous system in the development of obesity is a topic of continued interest.[8]

Studies of the early events in hypothalamic obesity have not been done regarding humans. We recently had the opportunity to study a child who developed the rapid onset of hyperphagia and obesity following an episode of meningoencephalitis. Insulin levels early in the clinical course of the illness were strikingly abnormal. These observations were consistent with the hypothesis that the central nervous system has important influence on the secretion of pancreatic insulin in humans and that hyperinsulinemia may foster the development of

the clinical syndrome of hypothalamic obesity.

REPORT OF A CASE

A 7-year-old boy presented with meningismus, papilledema, and mild left visual field neglect. His weight was 30 kg, and his height was 127 cm. The results of cerebrospinal fluid examination showed an opening pressure of 340 mm H_2O, a white blood cell count of 0.5×10^9/L (0.92 lymphocytes, 0.08 monocytes), a protein level of 1.28 g/L, and a glucose level of 2.5 mmol/L. An electroencephalogram showed bilateral, diffuse, background slowing, with attenuation of faster frequencies in the right posterior quadrant. Cranial computed tomography and magnetic resonance imaging were normal, with good visualization of the hypothalamus and third ventricular region. Herpes, mumps, leptospirosis, and *Mycoplasma* titers were unremarkable; cold agglutinins were negative. The Epstein-Barr virus titer was 1:1280, but the IgM titer was less than 1:10. The patient's first week of recovery appeared uneventful, except that the neurological consultant found him to be moderately uncooperative, with an exaggerated preoccupation with food.

He was discharged, but returned after 1 week, complaining of "eating and drinking constantly." He even ate vegetables, which he had previously disliked, but he did not eat nonfood items. He was described by his mother as becoming enraged when food was withheld, although not at inappropriate times. His weight had increased to 37.5 kg. He had abdominal distention with hepatomegaly and moderate tenderness over the liver. The results of neurological examination were normal, with resolution of the left neglect. It was noted that the patient would continue eating, even while cooperating with the examiner. A needle biopsy of the liver showed fatty infiltration. Baseline endocrine test results were as follows: T_4 thyroxine, 92 nmol/L (normal range, 58 to 155 nmol/L); T_3 resin uptake, 0.81 (normal range, 0.84 to 1.31); thyroid-stimulating hormone, 1.1 mIU/mL (normal range, 0.2 to 5.9 mIU/mL); morning plasma cortisol, 262 nmol/L (normal range, 166 to 690 nmol/L); and growth hormone, 276 pmol/L (normal level, <276 pmol/L). Prolactin level was mildly elevated (25 μg/L; normal range, 0 to 20 μg/L).

An oral glucose tolerance test revealed a normal glucose curve. However, baseline and stimulated insulin levels were markedly abnormal (Table 1). There were no symptoms suggestive of hypoglycemia during the test or at other times during the admission. Baseline growth hormone levels were undetectable, and there was no paradoxical rise of growth hormone in response to glucose.

The patient was discharged and readmitted 2.3 months after the onset of his illness for further evaluation. Basal metabolic rate was normal and caloric intake was approximately 6000 kcal/d. His weight had increased to 47 kg, and hyperphagia persisted. Oral glucose tolerance tests were repeated after 24-hour treatment with atropine and after 24 hours of diazoxide (Table 2). Carbohydrate tolerance had deteriorated, while insulin levels remained markedly elevated. The patient was discharged without pharmacological therapy.

Despite a trial of caloric restriction at home, the patient's weight climbed to 58 kg. Eighteen months after onset of the illness, the patient was readmitted for treatment with a strict diet of 700 kcal/d, which resulted in a weight loss of 7 kg. Hyperphagia persisted, although diminished, and the patient resumed weight gain at home to a peak of 74 kg, 10.4 months after the onset of the meningoencephalitis. A second inpatient trial of caloric restriction was attempted. Additional glucose tolerance tests were performed, which showed some "normalization" of insulin levels (Table 3). C-peptide levels were elevated, consistent with the level of insulin secretion. At the time of discharge, 3 months later, hyperphagia had considerably abated and his weight had dropped to 54 kg.

COMMENT

This young boy developed hyperphagia and obesity following an episode of meningoencephalitis. The clinical syndrome was consistent with hypothalamic obesity.[9] The postulated ventromedial hypothalamic damage may have occurred directly from the encephalitis[10] or indirectly from increased intracranial pressure.[9] Peripheral insulin levels were quite high, but the abrupt onset of the syndrome in association with the meningoencephalitis, the absence of hypoglycemia, and the gradual improvement of the hyperinsulinemia after a year do not support the presence of an insulin-secreting tumor. Inappropriate rage, which has been noted in experimental animals with ventromedial hypothalamic damage,[11] was not prominent in our patient, unless he was restricted from access to food. A similar pattern of behavior in a patient with a hamartoma invading the ventral hypothalamus has previously been reported.[3]

Hyperinsulinemia has been proposed as the major factor leading to hyperphagia and obesity in both humans and experimental animals with hypothalamic damage.[10,12] Bray and Gallagher[1] carefully examined humans with chronic obesity secondary to hypothalamic disease. In general, patients with hypothalamic obesity showed a glucose tolerance pattern and insulin response curve indistinguishable from those of individuals with exogenous obesity, ie, abnormal glucose tolerance, hyperinsulinemia, and insulin resistance. Obese patients with hypothalamic disorders, however, failed to normally suppress insulin in response to prolonged fasting.

The investigators concluded that hyperinsulinemia might be the initiating factor responsible for the hyperphagia and excessive fat deposition in these individuals.

Bucher et al[13] suggested that insulin might be responsible for the normal linear growth in patients who were deficient in growth hormone, following craniopharyngioma resection. They found an exaggerated insulin response to arginine infusions 1 year after tumor resection in children who exhibited excessive increase in height and weight. Early insulin measurements were not done, and glucose tolerance and insulin responses to glucose or fasting were not examined. Most of the patients in this subgroup were also noted to be hyperphagic, although this was not an invariable feature.

Our patient demonstrated interesting characteristics supporting the concept that hypothalamic regulation of insulin secretion is important in the evolution of hypothalamic obesity. Fasting hyperinsulinemia and exaggerated responses of insulin to glucose occurred early in the illness, preceding the development of massive weight gain.

Glucose tolerance was normal early in the course of his illness, and despite strikingly elevated insulin levels, there were no symptoms of hypoglycemia. Two months into his illness, the glucose tolerance tests showed a diabetic pattern, suggesting insulin resistance. Plasma cortisol level was normal, and the mechanism for the apparent insulin resistance was not clear. The early hyperinsulinemia could possibly have been the cause, rather than the consequence, of the obesity and hyperphagia.

Experimental[6] and clinical[14] studies have suggested that vagolytic therapy or vagotomy might be effective in modifying the weight gain in hypothalamic obesity. Pharmacological vagal blockade with the cholinergic antagonist, atropine, did not appreciably alter insulin responses in our patient. Diazoxide, which is used clinically to directly suppress insulin secretion by the pancreas,[15] also had no clear effect on the hyperinsulinemia. We did not have the opportunity to investigate the response of insulin to arginine infusion or fasting.

Unlike most cases of hypothalamic obesity, no other neurologic or neuroendocrine sequelae were noted in our patient.[10] Linear growth and sexual maturation will need to be closely monitored.

It is interesting that sequential examinations of this patient demonstrated a clinical and metabolic profile more closely resembling exogenous obesity. The biological determinants of most forms of obesity remain unknown, and the role of the central nervous system in caloric homeostasis is a topic of continuing interest.[8,12] Careful neuroendocrine examination of individuals with obesity associated with neurologic disorders may lead to better understanding of more common obesity problems.

Appearance on Computed Tomography, Magnetic Resonance Imaging, and Single-Photon Emission Computed Tomography

Matthew R. Moore, MD; Jeffrey L. Saver, MD; Keith A. Johnson, MD; Jorge A. Romero, MD

• We examined a patient who exhibited Gerstmann's syndrome (left-right disorientation, finger agnosia, dyscalculia, and dysgraphia) in association with a perioperative stroke in the right parietal lobe. This is the first description of the Gerstmann tetrad occurring in the setting of discrete right hemisphere pathologic findings. A well-localized vascular lesion was demonstrated by computed tomography, magnetic resonance imaging, and single-photon emission computed tomographic studies. The patient had clinical evidence of reversed functional cerebral dominance and radiologic evidence of reversed anatomic cerebral asymmetries.

(*Arch Neurol.* 1991;48:432-435)

The localization of focal cerebral lesions causing the tetrad of symptoms—finger agnosia, left-right disorientation, agraphia, and acalculia—has been debated since Gerstmann's name was first attached to the syndrome.[1,2] In almost all cases with focal pathologic appearance, the lesion has been localized to the left parietal cortex (angular and second occipital gyri,[1-3] supramarginal gyrus, and superior parietal lobule[4]; superior angular, supramarginal, and inferior parietal gyri[5]; and posterior perisylvian region[6]). Strub and Geschwind,[7] reviewing all reported cases in the world literature through 1983, found only four instances in which discrete *right* hemisphere lesions were suspected. All of these cases, however, were reported prior to the computed tomographic (CT) era, and precise neuroanatomic localization based on their reported clinical features is difficult.

We present anatomic and metabolic studies demonstrating a right hemisphere lesion in a sinistral woman who exhibited Gerstmann's syndrome in association with a well-localized vascular lesion confirmed by CT, magnetic resonance imaging (MRI), and single-photon emission computed tomography (SPECT), indicating regional cerebral perfusion and metabolism. This case is unique to the literature in its extensive imaging of an underlying *right* parietal stroke.

REPORT OF A CASE

A 57-year-old left-handed white woman was seen 2 days after the operative placement of a single coronary artery bypass graft and primary closure of an atrial septal defect. During the first day postoperatively, her recovery seemed uneventful, although she did not speak very much. On the second postoperative morning, the staff noted that she seemed to be having some difficulty expressing herself, particularly with word finding, and a neurological consultation was requested.

Her medical history was notable for an inferior wall myocardial infarction 1 year prior to admission and mild hypertension. She had had no history of cerebrovascular accidents, transient ischemic attacks, or seizures and was neurologically intact on admission. The patient had a college education. The family history was notable for left-handedness in the patient's daughter.

The general medical examination was notable for a midline sternotomy incision. No carotid bruits or cardiac murmurs were observed.

On neurologic examination, the patient was alert, oriented, and cooperative. Attention was relatively intact (digit span, six forward and four backward, and preserved ability to name months backward). Language testing revealed occasional hesitancies in spontaneous speech, with mild word-finding difficulties and occasional literal and verbal paraphasic error. Prosody was preserved.

Repetition was also mildly impaired, with some hesitation and occasional paraphasic substitutions. Confrontation naming of objects in the room and elements of the examiner's clothing and body parts was performed with better than 90% accuracy. Comprehension was unimpaired, as demonstrated by appropriate verbal responses to questions and correct execution of simple and multiple-step directives.

Striking right-left confusion was noted. Any task that required right-left discrimination led to hesitation, frustration, and repeated errors in execution. She was unable to identify digits on either hand: she could not reliably name the digits and made frequent errors in trying to follow commands instructing her to identify or utilize a specific digit on her own hand or on the hand of the examiner. She was aware of her difficulty and was frustrated by it. This finger-naming difficulty was in sharp contrast with her only mildly impaired ability to name objects and colors on confrontation, including low-frequency items. She was unable to perform any calculations, exclaiming "I can't visualize the math." Even very simple calculations, such as adding 12 + 13 or determining the number of nickels in 75 cents, could not be carried out. She appeared to understand the task and began calculating mentally; she then became confused, lost track of her work, and needed to start over. Her performance did not improve with the use of pencil and paper.

Reading was significantly impaired. The patient read sentences out loud slowly, ef-

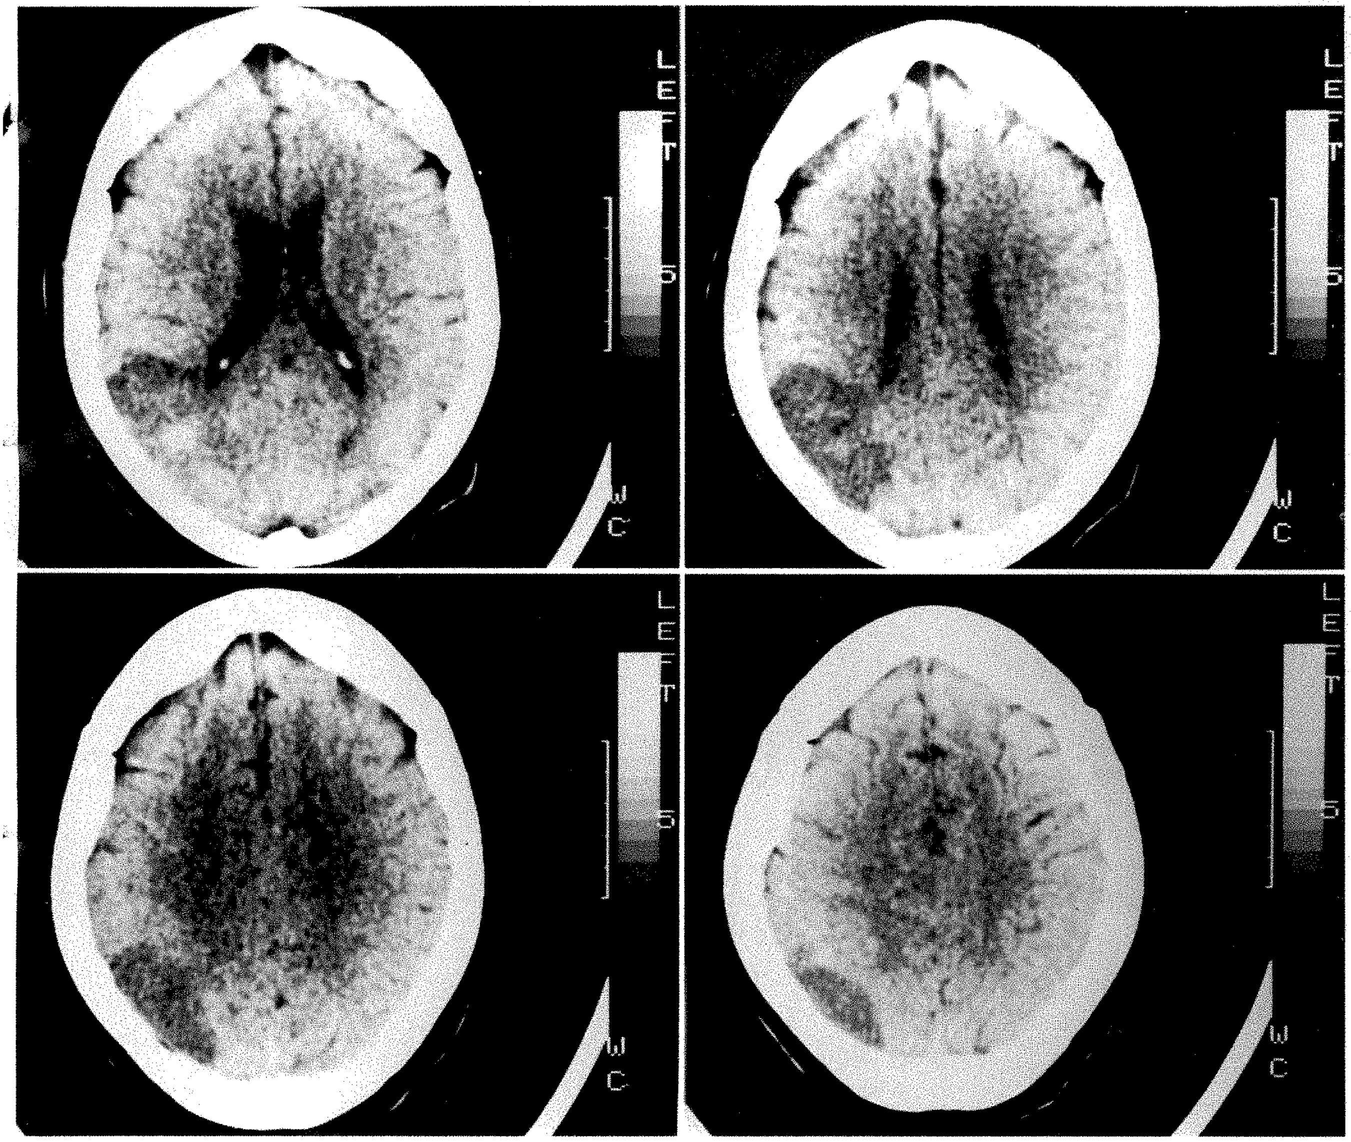

Fig 1.—Computed tomographic scans without intravenous contrast (axial, four adjacent 8-mm spaced images) taken on postoperative day 3 showing the right parieto-occipital low density in the angular gyrus (top left) extending superiorly just into inferior parietal gyrus and medially to the optic radiations.

fortfully, and monotonously, as if reading an unrelated list of words. Her comprehension of written passages was negligible. She was able to write only slowly and effortfully, with very poor penmanship, spelling errors, and omissions with drifting of the written line down and to the right on the page. When writing, she held her left hand in a "noninverted" posture. She evidenced no difficulty with constructions, drawing a clockface, and copying a cube with internal details accurately. Memory was unimpaired. She visually explored both sides of space, and there was no extinction to tactile simultaneous stimulation.

Results from the cranial nerve examination were notable for a left homonymous hemianopic visual field defect, denser in the inferior quadrant, and mild weakness of the lower face on the left side.

Examination of the extremities showed mild pronator drift of the left upper extremity but good strength on individual muscle-group testing and normal tone. Fine-motor control was unimpaired. Sensory testing to pin, touch, vibration, position, graphesthesia, and stereognosis was normal. Finger-to-nose, heel-to-shin testing was normal. Gait was normal. Reflexes were 1+ and symmetrical. Plantar responses were flexor.

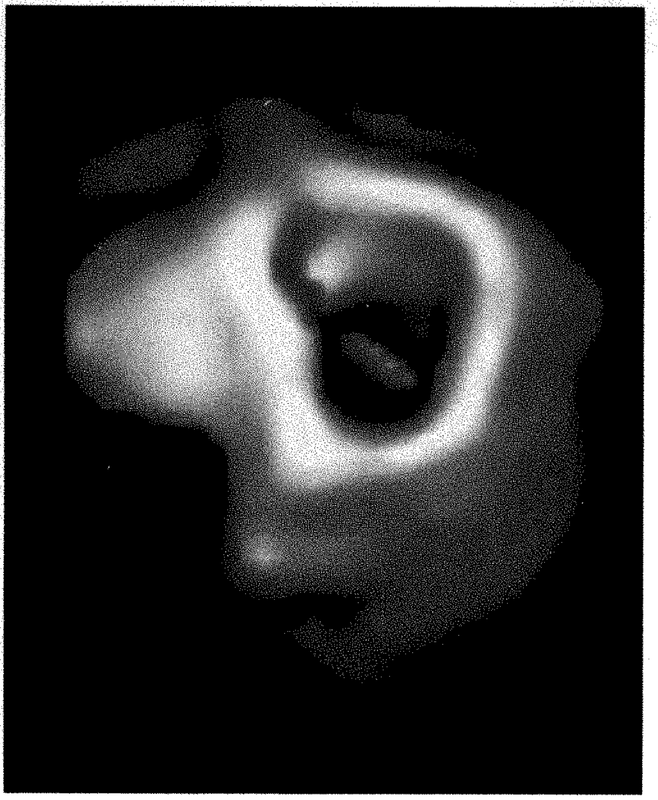
The patient scored −1.0 on the modified Oldfield handedness battery.

A perioperative cerebrovascular accident in the right middle cerebral distribution was suspected. A CT scan without contrast (Fig 1) on postoperative day 3 revealed a discrete right parieto-occipital wedge-shaped hypodensity (5 × 2.5 cm) in the angular gyrus. The area of lucency began at the level of the ventricular atrium and extended superiorly through three adjacent 8-mm axial CT images to the inferior parietal lobule and medially to the optic radiations.

On postoperative day 4, the patient's speech was fluent without paraphasic errors, and she had only minimal difficulty in repeating long gramatically complex sentences. Her facial asymmetry had resolved, and the field defect had improved to a moderate left inferior quadrant anopsia.

The patient underwent SPECT neuroimaging studies on postoperative day 7 with hexamethyl propylenamine oxime (technetium Tc 99m–HMPAO). The isotope uptake at 20 minutes after the injection shows a defect on axial view (Fig 2) of equivalent size to the hypodensity on CT scan. The three-dimensional surface reconstruction (Fig 3) places the hypoperfused region in the superior right parieto-occipital cortex (posterior angular gyrus) and underlying white matter.

On postoperative day 9, the patient underwent a cranial MRI scan in multiple planes for further evaluation of the vascular lesion. Figure 4 shows the coronal and axial images. The cerebral gyri are identified and show an



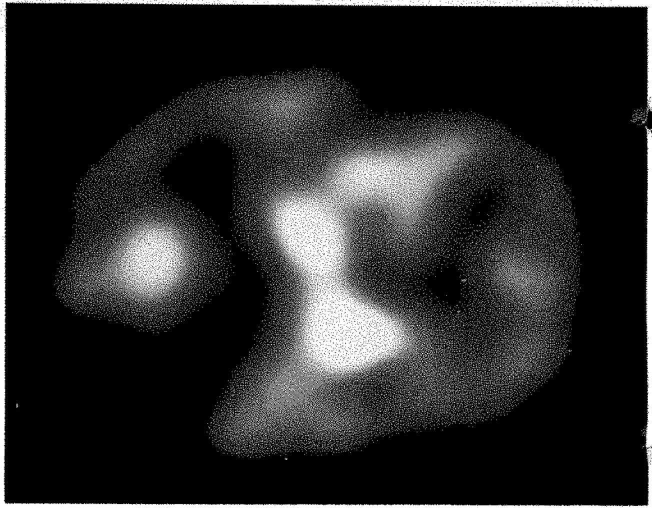


Fig 2.—Single-photon emission computed tomographic/hexamethylpropyleneamine (HM-PAO) axial image 20 minutes after injection on postoperative day 7. Note the similar perfusion defect in the right parieto-occipital region (patient's right on left of image). Color scale is such that yellow indicates regions with greatest HM-PAO concentration and dark blue indicates lowest HM-PAO activity.

Fig 3.—Three-dimensional surface reconstruction of the single-photon emission computed tomographic/hexamethylpropyleneamine images shown in Fig 2, viewed from the right posterior oblique angle. Note the shape and extensive defect inferior and posterior to the angular gyrus.

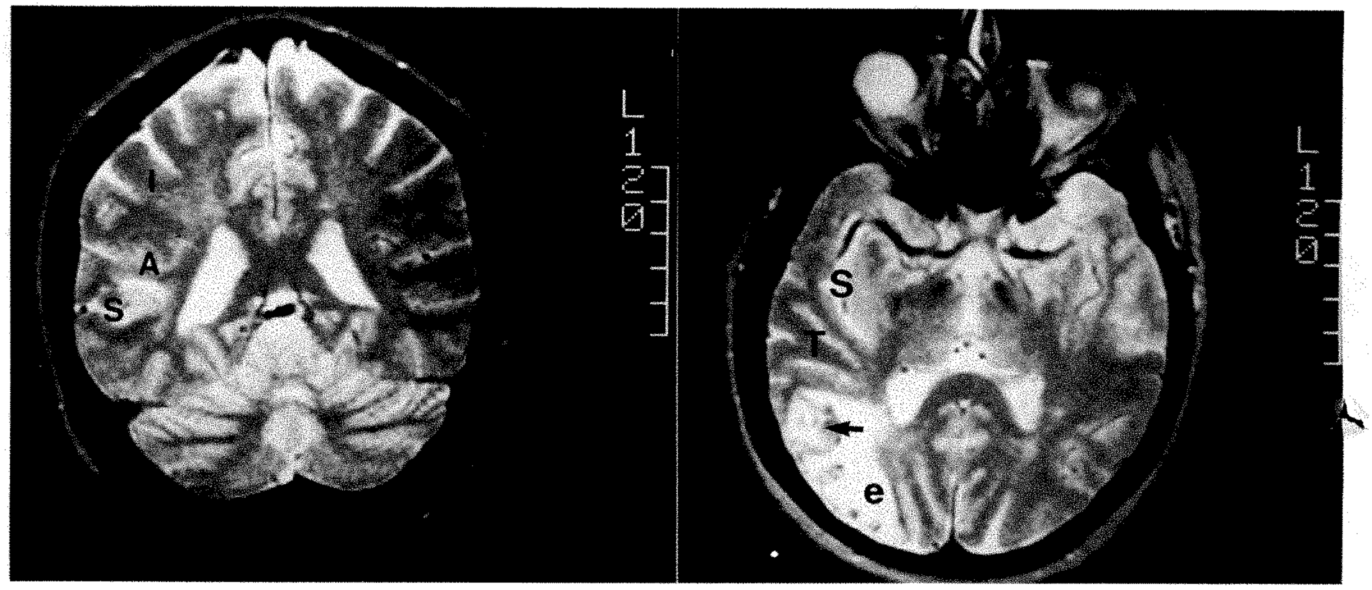

Fig 4.—Left, Magnetic resonance imaging (MRI), modified coronal plane (TR, 2000 milliseconds; TE, 35 milliseconds), anterior extent of increased signal of lesion. Inferior parietal gyrus (I), angular gyrus (A), and sylvian fissure (S) are indicated. Right, MRI, modified axial plane (TR, 2000 milliseconds; TE, 70 milliseconds), imaging through temporo-occipital lobes shows an area of heterogeneous cortical signal (arrow) in posterior inferior angular gyrus with extension of increased signal intensity (edema[e]) to adjacent occipital gyrus. The temporal operculum (T) and sylvian fissure (S) are shown.

area of heterogeneous cortical signal in the posterior inferior angular gyrus with extension of increased signal intensity (edema) to adjacent occipital gyri.

Both MRI and CT images were analyzed for anatomic asymmetries that have been proposed to correlate with functional cerebral asymmetry.[8,9] Standardized methods were employed to analyze sylvian fissure course,[10] fronto-occipital petalias,[11-13] and size of planum temporale (modified).[14] Each of these techniques demonstrated a reversal of the most common pattern of asymmetry found in right-handed subjects: (1) the posterior sylvian fissure on the right extended more horizontally and posteriorly than it did on the left (demonstrated in Fig 4, left); (2) on both MRI and CT studies, left frontal and right occipital lobes exhibited greater width and length (petalia) than did their counterparts; and (3) asymmetry of the posterior opercular demarcation, consistent with a larger planum temporale in the right hemisphere than in the left, was noted.

COMMENT

It is recognized that the four components of Gerstmann's syndrome in an individual patient may manifest to a variable degree.[7] In our patient, finger agnosia and left-right disorientation were prominently affected. Her agraphia, characterized by paragraphia with mispellings and syntax errors and spatial dysgraphia (poor word alignment across a page), was mild. Her acalculia was also severe, and of the type, anarithmetria,[2,7,15] that is most commonly associated with Gerstmann's syndrome. Additionally, our patient exhibited alexia and a mild posterior aphasia—deficits that have been noted to not infrequently accompany Gerstmann's tetrad (the *angular gyrus syndrome*). The major impairment in finger identification, left-right discrimination, and calculations was disproportionate to the mild deficit in oral language function. Evidence of constructional apraxia or hemispatial neglect was absent.

We believe that ours is the first patient to be described with Gerstmann's syndrome resulting from a focal right hemisphere lesion that has been fully documented by CT, MRI, and SPECT studies. Strub and Geschwind's[7] review of all reported cases through 1983 noted only four patients suggested to have discrete right hemisphere lesions, with 68 patients with left hemisphere lesions, 20 with bilateral lesions, and four with either left hemisphere or bilateral lesions. Our review of the literature since has yielded no additional right hemisphere cases. All four right hemisphere cases preceded the advent of modern neuroimaging. The two patients described by Heimberger et al[16] are listed in a table but are not clearly identified in the accompanying individual case descriptions. It appears likely that one of the cases they listed as right hemisphere was a patient described as having a large right hemisphere glioblastoma with midline shift and an electroencephalogram displaying slowing on the left side; thus, this patient almost certainly had undergone a pathologic event bilaterally. Heimberger et al[16] provided no detailed description of a second patient with clinical evidence of a discrete right hemisphere lesion. In Kinsbourne and Warrington's[17] case, localization was based on accompanying clinical signs and electroencephalographic findings—no confirmatory anatomic studies were provided. Hermann and Potzl's[18] 1926 case had a right occipital tumor discovered at surgery, without exploration or postmortem examination of the left hemisphere to exclude a bilateral process.

Gerstmann suggested that the symptom cluster of finger agnosia, right-left disorientation, agraphia, and acalculia indicated lesions in the dominant parietal lobe, situated in the great proportion of right-handers and most left-handers in the left hemisphere. We hypothesize that our patient had strongly reversed functional cerebral lateralization so that a right parietal lesion could produce the constellation of signs of Gerstmann's syndrome. Our patient was strongly left-handed (modified Oldfield handedness score, −1). A family history of left-handedness in a first-degree relative was known. (Evidence of a genetic component to determination of handedness has been reviewed by Levy.[19]) The patient wrote with a noninverted hand posture, which has been suggested to indicate likely contralateral hemispheric (here, right hemispheric) dominance for speech.[20] The patient also experienced alexia and mild posterior aphasia following her isolated right hemisphere insult, further suggesting that she had had major representation of language function in the right hemisphere.

Moreover, a number of investigators have identified anatomic asymmetries that may correlate with functional cerebral asymmetry.[8-14] Our patient exhibited reversed asymmetry for several of these anatomic findings. The posterior sylvian fissure on the right extended more horizontally and posteriorly than did its counterpart, suggesting that the temporal and parietal opercula were larger on the right than on the left. The planum temporale, a major component of the temporal speech region of Wernicke, was larger in the right hemisphere than in the left. Thus, our patient exhibited both a pattern of anomalous functional motoric and linguistic dominance and a reversal of anatomic brain asymmetries that may comprise the biologic substrate of functional lateralization.

In addition to the variable deficit severity of each component in Gerstmann's syndrome,[7] some have remarked that deficit improvement occurs at different rates longitudinally.[21] Similarly, we noted improvement in this patient's writing ability and right-left orientation at 1 week postoperatively (postvascular event).

In this well-documented instance of a focal right hemisphere lesion producing Gerstmann's syndrome, the pathologic event was situated primarily in the posterior parietal lobe. Thus, this case provides further evidence to supplement the findings drawn from numerous previously reported left hemisphere cases that the lesion most likely to produce Gerstmann's syndrome is placed in the dominant posterior parietal region.

The authors thank Mathias-Victor Schromm for bibliographic assistance.

Neurologic Complications of the Tryptophan-Associated Eosinophilia-Myalgia Syndrome

Lynn M. Tolander, MD; Colin R. Bamford, MD; Mark T. Yoshino, MD; Samuel Downing, MD; George Bryan, MD

• A case of tryptophan-associated eosinophilia, central nervous system complications, and multiple white matter lesions by magnetic resonance imaging is presented. Eosinophilia regardless of its cause should be included within the differential of patients exhibiting periventricular white matter lesions.

(*Arch Neurol.* 1991;48:436-438)

In November 1989, an article disclosed an epidemic of eosinophilia-myalgia syndrome first recognized in New Mexico,[1] but subsequently noted to be widely distributed across the entire United States.[2] The condition was associated with the ingestion of the essential amino acid tryptophan. The pathogenic mechanisms underlying this association have yet to be elucidated.

Symptoms reported included myalgia, subjective weakness, fever, arthralgia, dyspnea, rash, edema, and pneumonia. This was by definition accompanied by an eosinophilic leukocyte count of more than 2×10^9/L.[1] Thirteen deaths have been attributed to this condition.[3]

REPORT OF A CASE

A 46-year-old white woman was admitted to a community hospital on October 19, 1989, for right-sided weakness. One week prior she had fallen, landing on her coccyx. A few days later she developed right arm and face numbness and weakness with progression to the right leg by the day of admission.

The only medication that she claimed to be taking on admission was vitamin E. Her medical history was unremarkable. She had a 25-pack-year history of smoking, but no history of alcohol or drug abuse. On review of systems, she reported recent onset of frontal headache, blurred vision, and right shoulder aches.

On initial examination she was not in acute distress and had normal vital signs. Examination of her skin disclosed a streaky, erythematous rash over the buttocks and legs. On neurologic examination, her mental status was normal. Cranial nerve testing revealed a mild right central seventh nerve palsy and diminished sensitivity to sharp stimuli over the right side of her face. The patient's strength was graded 0/5 in the right upper extremity and 4/5 in the right lower extremity. Reflexes were 2+ throughout and plantar responses were flexor. Sensory examination demonstrated decreased perception of sharp stimuli on the right side of her body. There were no abnormal cerebellar signs. She had a right hemiparetic gait. The remainder of the physical examination was unremarkable.

Results of admission laboratory investigations were significant for a white blood cell count of 19.4×10^9/L (normal, 4 to 10×10^9/L), with a differential of 0.5 segmented neutrophils (normal, 0.54 to 0.62), 0.15 lymphocytes (normal, 0.25 to 0.33), 0.03 monocytes (normal, 0.01 to 0.13), and 0.32 eosinophils (normal, 0.01 to 0.05). Results of the liver function tests were nonspecifically abnormal.

An initial computed tomographic scan of the head with and without contrast demonstrated an irregular area of decreased attenuation in the deep left frontal lobe without enhancement or mass effect, suggesting an ischemic infarct. Her two-dimensional echocardiogram and carotid duplex ultrasound studies were unremarkable.

A lumbar puncture was performed with the following results: protein, 0.69 g/L (normal, 0.15 to 0.45 g/L); glucose, 3.4 mmol/L (normal, 2.2 to 4.4 mmol/L); white blood cells, 0.001×10^9/L (normal, 0 to 0.005×10^9/L); and red blood cells, 7×10^{12}/L (normal, 0 to 10×10^{12}/L). *Trichinella* serologic examination and stool for ova and parasites were negative. An evaluation for occult malignancy included a chest roentgenogram, abdominal computed tomographic scan, and mammogram, all of which were negative. A vasculitis screen included the following: erythrocyte sedimentation rate, serum protein electrophoresis, antinuclear antibody, and rheumatoid factor, all of which were normal. Serum human immunodeficiency virus, toxoplasmosis, coccidioidomycosis, and *Aspergillus* titers as well as VDRL and *Candida* antigen assays were negative.

A magnetic resonance imaging scan of the head disclosed multiple focal areas of abnormally increased signal intensity within the deep white matter and corpus callosum (Figs 1 through 3) as well as a focal area of increased signal intensity within the left parietal lobe.

The patient was transferred to the University Medical Center in Tucson, Ariz, on October 26, 1989, for further investigation. The examination at the time of transfer revealed a spastic right hemiparesis and bilateral Babinski signs. Based on the magnetic resonance imaging appearance, which raised the possibility of multiple sclerosis, a second lumbar puncture was performed and showed the following results: protein, 0.3 g/L; glucose, 3.9 mmol/L; white blood cell count, 0.008×10^9/L (0.99 monocytes); red blood cell count, 3×10^{12}/L; IgG, 0.018 g/L (normal, 0.01 to 0.04 g/L); and two distinct oligoclonal bands. Visual evoked responses were normal, and median somatosensory responses revealed only slowing of intracortical conduction consistent with the patient's left-sided symptomatic lesion. An electroencephalogram was normal. Dis-

Fig 1.—This T$_2$-weighted axial magnetic resonance image shows an abnormal area of increased signal (arrow) in the right side of the splenium of the corpus callosum (TR = 2500, TE = 30, 0.6 Tesla).

charge diagnoses were possible multiple sclerosis vs eosinophil-induced neurotoxicity, and peripheral eosinophilia of unclear etiology.

Approximately 1 month later, when news reports of tryptophan associated with eosinophilia surfaced in the lay press, the patient disclosed that she had been taking 1.5 to 2 g of tryptophan at bedtime for the preceding 4 to 6 months. Use of the drug had been inadvertently discontinued on admission to the hospital. No treatment was given, and she has had no further neurologic events. Five months after initial presentation her white blood cell count was 10.8×10^9/L, with 0.1 eosinophils, signifying a reduction in her absolute eosinophil count from 6208 to 1080 cells. However, at this point the patient returned with an erythematous, edematous lower extremity rash and sclerotic plaques consistent with eosinophilic fasciitis (confirmed by skin and muscle biopsy). The creatine kinase level was normal; however, the aldolase level was elevated to 45 U/L (normal, 0 to 6 U/L). She was agreeable to starting steroids. A follow-up magnetic resonance imaging 5 months after presentation revealed that the previously noted white matter lesions had diminished in size and evolved into small infarcts (Fig 4).

COMMENT

Our patient has been extensively evaluated excluding the usual causes of eosinophilia other than the ingestion of tryptophan. The distribution of the patient's multiple central nervous system lesions is highly atypical of multiple sclerosis due to their location within the splenium of the corpus callosum and within the cerebral gray matter. Likewise, the evolution of the lesions on magnetic resonance imaging is atypical for multiple sclerosis and is more suggestive of small infarctions. The clinical course was one of a subacute monophasic progressive illness, which would speak against a diagnosis of clinically definite multiple sclerosis. The two oligoclonal bands may represent a nonspecific inflammatory reaction. Therefore we believe this to be the first reported case of central nervous system involvement by tryptophan-associated hypereosinophilia.

As of February 9, 1990, there had been 1269 cases of tryptophan-associated eosinophilia reported in the United States.[3] Due to the frequent complaint of muscle pain, the disease has been called the eosinophilia-myalgia syndrome. The current median age of those affected is 48 years, and the median dose of tryptophan is 1500 mg/d. Eighty-four percent are female and 96% are non-Hispanic whites.[4] Rash and edema have been reported in over 50%.[1,3] Elevated liver function tests were noted in 51%.[3] Our patient fits the demographic pattern; however, she has a pronounced central nervous system involvement and an absence of severe myalgias.

A review of the literature revealed reports of peripheral and central nervous system involvement by the idiopathic hypereosinophilia syndrome. With respect to the peripheral nervous system, clinical patterns of multiple mononeuropathy, distal symmetrical motor neuropathy, distal symmetrical sensory neuropathy, and radiculopathy have been reported.[5-9] Nerve biopsy or autopsy has shown a variety of histopathologic findings consistent with wallerian degeneration,[9] axonal degeneration,[5] demyelination, and vasculitis.[6] The pathogenetic mechanisms proposed have included ischemia on either a vasculitic[5-7] or cardioembolic basis,[7] and also neurotoxicity.[5,7,9]

With regard to the central nervous system, clinical patterns of seizures,[7] dementia,[7,9,10] and cerebral infarction[7,9] have been described. Computed tomographic scans in these cases have shown infarcts,[9] areas of contrast enhancement,[7] atrophy,[7,9] and the appearance of demyelination.[7] In 1989 Kaplan reported a case with periventricular areas of increased signal intensity on magnetic resonance imaging. The pathogenetic mechanisms postulated include thromboembolization,[7-9] eosinophil infiltration,[9] and neurotoxicity.[7,9,10]

Although the term *neurotoxicity* initially seems rather indefinite, it has been well established that the eosinophil contains cytotoxic granules that release eosinophil cationic protein (partially responsible for thromboembolism), neurotoxic protein, and major basic protein.[11] In 1979 Durack et al[12] injected cells from patients with hypereosinophilic syndromes into either the cerebral hemisphere or subarachnoid space of rabbits and guinea pigs. Examination of the brains revealed loss of Purkinje cells, spongy degeneration of the cerebellum, brain stem and spinal cord, and an occasional axonal degeneration of the peripheral nerves. It seems reasonable to hypothesize that these toxic granules played a pathogenic role in our patient, perhaps by creating a vasculitis leading to microinfarctions.

Although tryptophan itself has been

demonstrated to exhibit in vitro a direct neurotoxicity, probably related to indoleamine dioxygenase metabolites,[13-15] we believe that the weight of evidence favors a role played by the eosinophilia documented in this patient.

It should be noted that although tryptophan was discontinued at the time of the initial admission, the peripheral eosinophilia only gradually improved, leaving an eosinophilic fasciitis 5 months after presentation. This observation would lend support to early aggressive steroid therapy.

We presented a patient, whose clinical presentation was suggestive of a stroke syndrome, but in whom there existed striking eosinophilia and multiple central nervous system lesions demonstrated by magnetic resonance imaging. To our knowledge this represents the first reported case of central nervous system involvement due to tryptophan-associated eosinophilia. This case illustrates the importance of specifically inquiring about the ingestion of tryptophan during the evaluation of a patient with multiple white matter lesions, as patients may not volunteer information about their use of nonprescription medications.

Magnetic Resonance Imaging of Fourth Ventricular Epidermoid Tumors

William A. Wagle, MD; Bruce Jaufmann, MD; J. Ernest Mincy, MD

• Two pathologically proved cases of epidermoid tumor of the fourth ventricle are presented; clinical history and computed tomographic, magnetic resonance imaging, and histopathologic findings are included.

(*Arch Neurol.* 1991;48:438-440)

Epidermoid tumors arise from the inclusion of ectodermal elements at the time of closure of the neural groove, resulting in a heterotopia of such elements. Within the central nervous system, these tumors occur most frequently in descending order in the cerebellopontine angle, parapituitary region, diploe, fourth ventricle, petrous bone, and intraspinal space.[1] The name *pearly tumor* has been applied to this tumor because its smooth capsular surface sometimes has a mother-of-pearl appearance. It has also been called a cholesteatoma because the soft, white, waxy material that makes up the tumor is rich in cholesterol crystals. This material is the result of progressive desquamation and breakdown of keratin from the epithelial lining of the cyst. Numerous reports describing the computed tomographic (CT) findings of fourth ventricular epidermoid tumors generally agree that these tumors cause dilatation of the fourth ventricle, have a density less than water but greater than fat, and show no evidence of contrast enhancement.[2-6] Both cases in this report showed similar CT characteristics, and on magnetic resonance imaging (0.5 T), the tumors were hypointense relative to brain parenchyma on T_1-weighted images (short repetition time; short echo time) and hyperintense on T_2-weighted images (long repetition time; long echo time).

REPORT OF CASES

CASE 1.— A 60-year-old man had a 15-year history of dizziness, but in the few months prior to surgery he became ataxic enough to warrant the use of a cane, and he complained of mild headaches. On examination, it was observed that he had sustained nystagmus on right and left lateral gaze, with moderate upbeat nystagmus. His gait was broad based, and appendicular testing of the upper extremities revealed mild decreased function. The findings of the remainder of the examination were normal. A CT scan showed a low-density, nonenhancing, well-marginated mass within an expanded fourth ventricle, associated with hydrocephalus (Fig 1, top left). Magnetic resonance imaging showed a well-marginated, homogeneously low-signal mass within the fourth ventricle on sagittal (Fig 1, top right) T_1-weighted images. On axial T_2-weighted images, the mass was hyperintense and there was no peritumoral edema (Fig 1, bottom left). At surgery, a white tumor with the consistency of cottage cheese

From the Departments of Radiology (Dr Wagle), Neurology (Dr Wagle), and Neurosurgery (Drs Jaufmann and Mincy), Albany (NY) Medical Center.

Reprint requests to Department of Radiology, Albany Medical Center, New Scotland Avenue, Albany, NY 12208 (Dr Wagle).

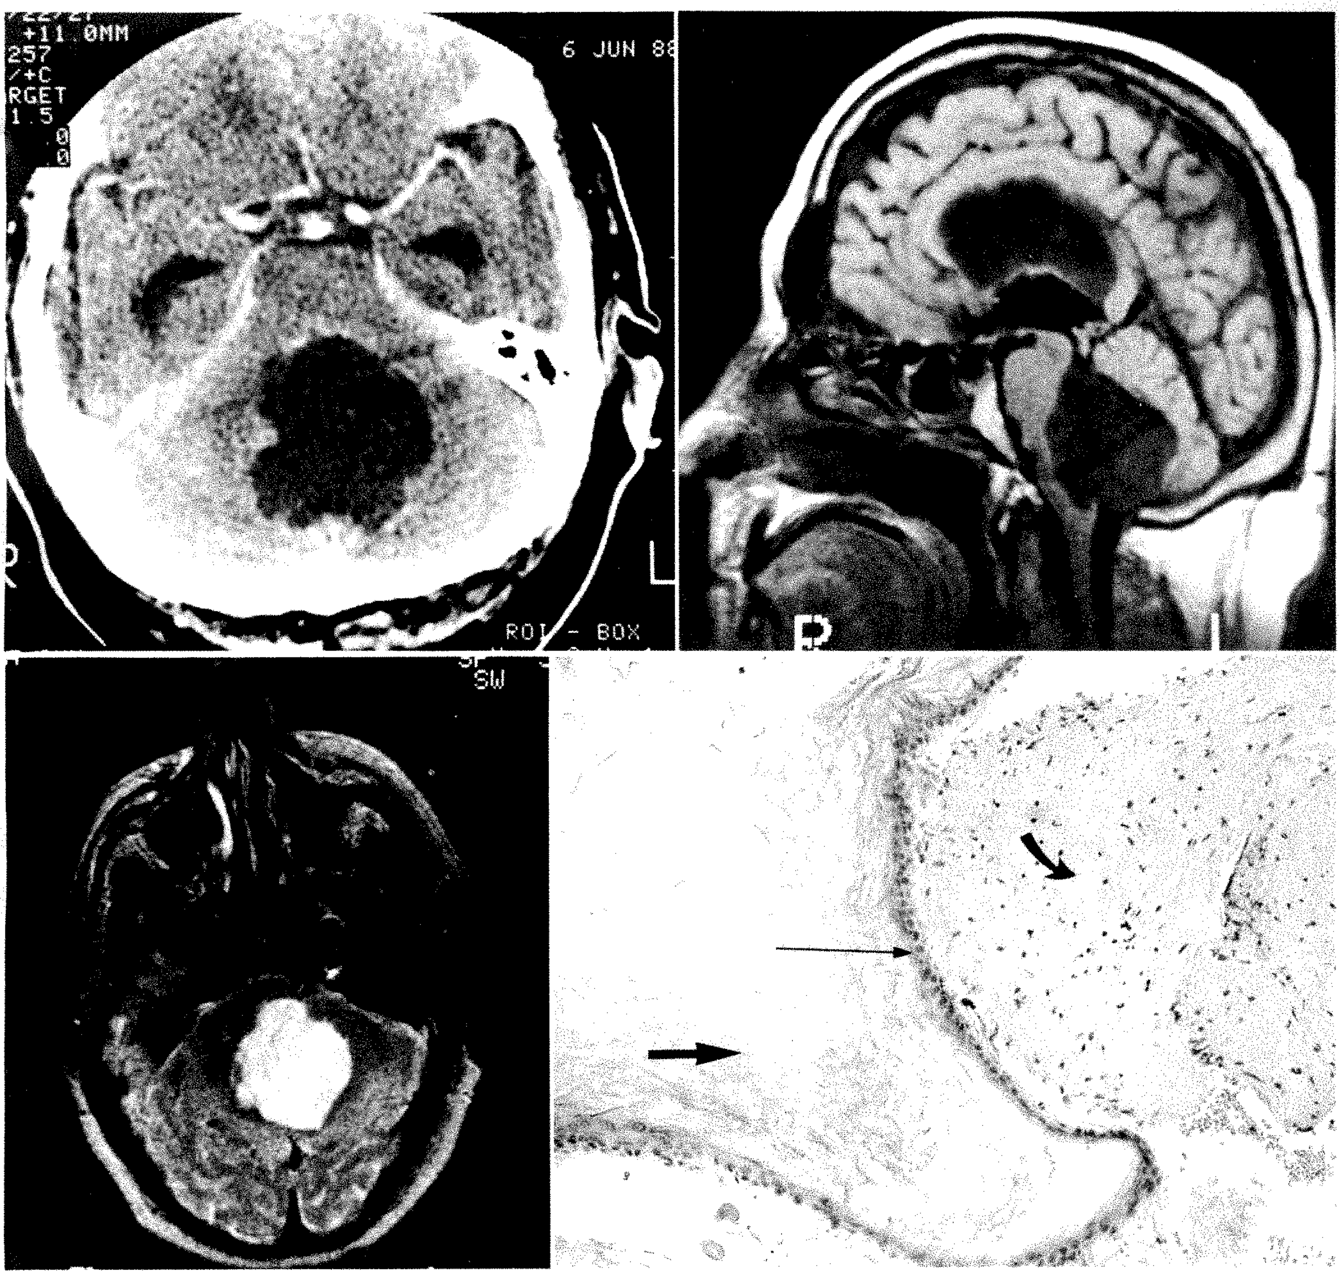

Fig 1.—Top left, Enhanced computed tomographic scan shows well-marginated, nonenhancing, low-density mass within the fourth ventricle. Top right, Sagittal magnetic resonance image (short repetition time; short echo time) shows low-signal tumor within the fourth ventricle with compression of the brain stem and cerebellum. Bottom left, Axial magnetic resonance image (long repetition time; long echo time) shows high-signal tumor within the fourth ventricle. Bottom right, Black-and-white photomicrograph (high magnification) of a hematoxylin-eosin preparation showing lamellar keratin debris (heavy straight arrow), stratified squamous epithelium (long thin arrow), and outer layer of collagenous material (curved arrow).

was present within the fourth ventricle, clearly separated from the cerebellar hemispheres and vermis. The microscopic appearance of the tumor was typical of an epidermoid. The lining of the cyst was composed of a simple stratified squamous epithelium supported by an outer layer of collagenous tissue. Progressive exfoliation of keratinous material toward the interior of the cyst produced the characteristic lamellar appearance (Fig 1, bottom right).

Case 2.— A 44-year-old woman presented with several months of ataxia. On physical examination, she had diplopia, nystagmus on extreme lateral gaze to either side, and mild appendicular ataxia in the right arm and leg. The findings of the remainder of the neurologic examination were normal. Magnetic resonance imaging demonstrated findings identical to those in case 1. On the sagittal T_1-weighted image (Fig 2, top), the fourth ventricular tumor had low-signal intensity, and on the axial T_2-weighted image, it demonstrated homogeneously high-signal intensity without peritumoral edema (Fig 2, bottom). An angiogram (not shown) showed mass effect without evidence of stain, and a CT scan (not shown) showed a nonenhancing, low-density mass within the fourth ventricle. At surgery, an exophytic white tumor was found in the fourth ventricle, and the findings of gross inspection were consistent with an epidermoid tumor. Histologic examination demonstrated the characteristic findings of an epidermoid tumor, similar to those seen in Fig 1, bottom right.

COMMENT

The CT characteristics of epidermoid tumors of the fourth ventricle

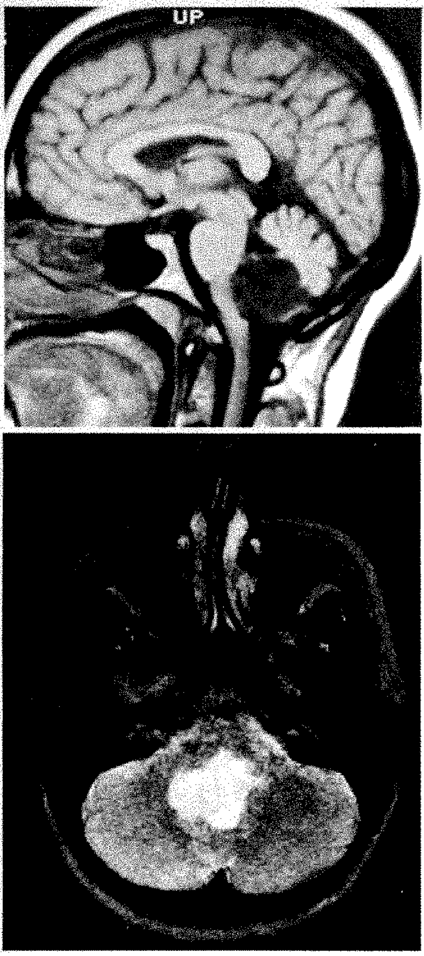

Fig 2.—Top, Sagittal magnetic resonance image (short repetition time; short echo time) shows expansion of the fourth ventricle by a low-signal mass. Bottom, Axial magnetic resonance image (long repetition time; long echo time) shows high-signal tumor.

have been described in detail.[2-6] Smooth margination, mass effect, and lack of peritumoral edema are common with these lesions.

Horowitz et al[7] studied five patients with epidermoid tumors and found that three tumors demonstrated high-signal intensity and two tumors low-signal intensity on T_1-weighted images. All five surgical specimens were analyzed using C-13 magnetic resonance imaging spectroscopy. Epidermoids with short T_1 values (white epidermoids) had negative CT values and high lipid content on magnetic resonance imaging spectroscopy. The predominant component was mixed triglycerides, but there was no significant amount of either free fatty acid or cholesterol. Epidermoids with long T_1 values (black epidermoids) had CT values approximating water, and exhibited a reduced lipid content on spectroscopy. Yuh et al[8] described two cases (one proved) of epidermoid tumor of the fourth ventricle; both were hypointense on T_1-weighted images and hyperintense on T_2-weighted images. Steffey et al[9] described five cases of intracranial epidermoid tumor, none of which occurred in the fourth ventricle. All five were hypointense on T_1-weighted images and hyperintense on T_2-weighted images.[9] Tampieri et al[10] described nine patients with epidermoid cysts (five proved), two of which were located within the fourth ventricle. Two of the nine cases were studied on a 0.5-T unit and the remaining seven on a 1.5-T system, but the authors did not indicate if the fourth ventricular tumors were studied on the 0.5- or the 1.5-T system.

Russell and Rubinstein[1] do not mention different characteristics of epidermoid tumors depending on their anatomical position within the brain or skull. One can assume that the signal characteristics of an epidermoid tumor within the fourth ventricle are the same as those of one within the cerebellopontine cistern. Those epidermoids within the diploe might have mixed-signal intensity depending on the amount of marrow fat within the tumor. Multiple cysts may be intermixed with desquamated epithelium. It is progressive desquamation that leads to slow expansion of the tumor. The differentiating feature between an epidermoid tumor and a dermoid tumor is the presence of skin appendages in the latter. Dermoid tumors contain hair follicles, sebaceous glands, and apocrine glands. The escape of the contents of a dermoid or epidermoid cyst into the cerebrospinal pathway can excite a granulomatous form of meningitis in which there is a foreign body giant cell reaction to particles, particularly the cholesterol granules.

In our series and in several others, the signal pattern has been low-signal intensity relative to brain parenchyma on T_1-weighted images (short repetition time; short echo time) and high-signal intensity on T_2-weighted images (long repetition time; long echo time). There is frequently a considerable cystic (water signal) component within these tumors that will produce low-signal intensity on T_1-weighted images. Cholesterol crystals should not produce high-signal intensity on T_1-weighted images. Sebaceous glands produce proteinaceous liquid that may show increased signal on T_1-weighted images. These glandular structures are present in dermoids and teratomas but not in epidermoids. We speculate that the signal characteristics of epidermoid tumors of the fourth ventricle show hypointensity on T_1-weighted images because the tumor is composed of desquamated squamous epithelium that contains keratin and because there is frequently a cystic (water) component. In addition, the outer layer of collagenous tissue should not produce high-signal intensity on T_1-weighted images.

Fourth ventricular epidermoid tumors are benign tumors that exert mass effect, have no peritumoral edema, and may be associated with hydrocephalus. At 0.5 T, they demonstrate decreased-signal intensity relative to brain parenchyma on T_1-weighted images and hyperintensity on T_2-weighted images.

Professional Opportunities

NEUROLOGIST: Excellent opportunity for board-certified/board-eligible neurologists to join two existing neurologists in a stimulating, busy practice. Marquette General Hospital is a 321-bed regional referral center, with a comprehensive neurophysiology department and state-of-the-art technology that includes magnetic resonance imaging and CT scanning, and a hospital-based family practice residency. Medical students from Michigan State University's College of Human Medicine are regularly assigned to the hospital and offer an opportunity for teaching. Marquette General Hospital and its medical staff are committed to building a center of excellence in the neurosciences and have the necessary financial resources. The development of these services will require the leadership and cooperation of physicians in the field of neurology, neurosurgery, psychiatry, physical medicine and rehabilitation. Salaried and private practice positions are available. If this special opportunity is of interest to you, please send CV to: Robert J. Raica, Marquette General Hospital, 420 West Magnetic Street, Marquette, MI 49855.

BE/BC NEUROLOGIST

To join an associate neurlogy practice in south-central Nebraska. This opportunity comes with the full support of your colleages and offers exceptional life style and practice potential. Income guarantee, relocation, MP, office paid. Send CV or contact: Armando L. Frezza, President, Medical Support Services, 8806 Balcones Club Drive, Austin, TX 78750. Office (800) 288-7420; FAX (512) 331-6741.

BC/BE NEUROLOGIST NEEDED — California. Excellent opportunity to establish your own private practice with no investment, guaranteed income. Strong referral base. Proficiency in EEG/EMG required. Well equipped, 112-bed, full-service hospital. Our service area population is now 90,000; a growing area with new businesses and stable economy. Located in central California near Sequoia National Park, Tulare offers an excellent family-oriented lifestyle and all expected amenities. Beautiful homes close to hospital and office are affordably priced. Good schools, many community activities and abundant recreation including golf, tennis, mountain and equestrian activities. Easy access to all California's major metropolitan and resort areas. Please contact: Tulare District Hospital Physician Recruiting Office, P.O. Box 90112, Los Angeles, CA 90009. (800) 468-2687.

DOCTORS IN YOUR SPECIALTY are the best market for used/serviceable equipment that may be surplus to your needs. Advertise this equipment in an AMA specialty journal and reach your market. Call our "Classified Advertising" office toll free: National (800) 237-9851; in Florida (800) 553-8288.

NEUROLOGIST to join dynamic, midwest neurology group. This very busy practice is seeking an energetic neurologist with a strong interest in the clinical care of patients. This opportunity is located in a desirable, midwestern community abundant in cultural and sporting activities. The practice has a well-equipped radiology department with MRI and CT, and also, neurophysiology and neuropsychology departments. The appropriate candidate must be energetic, pleasant, BC/BE, with EMG experience. Please send curriculum vitae to: Box #814, c/o AON.

MAUI ORTHOPEDIC and Sports Medicine seeks neurologist to establish independent practice. Contact: William Gfeller, 450 Hookahi Street, Wailuku, Maui, HI 96793. (808) 244-5541.

Professional Opportunities

CHICAGO SUBURBAN solo practitioner with a busy practice seeking a full-time BC/BE clinical neurologist. EMG skills required. Immediate opening. Wonderful opportunity to expand with possible early partnership. Reply with CV to: Yvonne Jurcik, MD, 125 East Lake Cook Road, Buffalo Grove, IL 60089.

EXCELLENT OPPORTUNITY for BC/BE neurologist to join 80-physician, comprehensive, multi-specialty group in San Francisco Bay Area. Large, varied referral base from pediatrics, IM, FP, and surgery. EMG/NCV, EEG, evoked response testing, CT, MRI, radiology support all available on site. Opportunity to interface with sepcialists of all types including neurosurgeons. Major university teaching affiliation encouraged and possible. Close proximity to 400-bed full service, modern hospital serving population of 300,000. Competitive guaranteed salary with bonus productivity plan for initial 18 months leading to partnership track. Extensive benefit package including housing incentives. Unique cultural, recreational and educational opportunities. Send CV to: Gary D. Zweig, MD, Recruitment Chairman, Sunnyvale Medical Clinic, P.O. Box 3496, Sunnyvale, CA 94088-3496.

KANSAS — Board-certified, board-eligible neurologist to join child neurologist in rebuilding a three-person practice in the largest city in Kansas. Three large, well-equipped hospitals available for resident and undergraduate medical education. Located in clean, progressive community described as the franchise capital of the country. Competitive salary and benefits available. Send CV to: Richard C. Gilmartin, MD, 2620 East Central, Wichita, KS 67214.

NEUROLOGIST

Minneapolis/St. Paul — BC/BE adult neurologist wanted to join four other neurologists in a diverse practice consisting of both inpatient and outpatient settings. Group Health, Inc. is a non-profit, member governed HMO with one of the largest multi-specialty group practices in the Midwest. Our physicians are given the ability to focus on practicing high quality, cost-effective medicine in an environment that is relatively free of administrative duties. The Twin Cities are recognized as one of the best areas in the country to raise a family. The communities provide excellent schools, countless cultural events, numerous recreational activities, and a myriad of lakes and parks.

To inquire, please call: (612) 627-6122.
Or send CV to:

Group Health, Inc.
Attention: Ann Johnson
2829 University Avenue SE
Minneapolis, Minnesota 55414

JULY 1991 — ASSOCIATE WANTED. Outstanding opportunity. $200K net probable by end of first year. Fully equipped neurologic institute. Only the best need apply. Send CV at once: Southeastern Neuroscience Institute, Inc., 5143 University Boulevard, West, Suite 3, Jacksonville, FL 32216-5939. (904) 733-0707; FAX (904) 730-9173.

THIRD NEUROLOGIST, BC/BE, desired for growing neurology practice in southern Michigan. EMG/EEG expertise and strong clinical skills required. Wide referral base. Equipped neurophysiological laboratory available. Exceptional lifestyle and cultural resources. Attractive salary and incentives leading to parternship in one year. Please write to: Neill S. Hirst, MD, 250 West Eisenhower Parkway, Suite 100, Ann Arbor, MI 48103. Or call: (313) 665-6638.

NEUROLOGIST

BC/BE neurologist wanted to join a busy neurology group in the northeastern region.

Situated in a beautiful summer/winter recreational area, in close proximity to several major cities.

This is an excellent professional opportunity in a rapidly growing community.

Highly competitive salary and fringe benefits with early partnership.

Please reply to:

Box #816, c/o AON

Professional Opportunities

CHICAGO — BC/BE neurologist to join existing practice. Highly motivated individual with strong clinical skills and EMG/EEG expertise needed to join two busy neurologists. Very strong medical school affiliation with teaching responsibilities for neurology and internal medicine, residents and medical students. Large referral base. Excellent benefit package. Please provide CV. Please contact: Box #818, c/o AON.

SEEKING ENERGETIC BE/BC NEUROLOGIST to join three adults and one child neurologist. Prefer someone with interest in general neurology and special interest and training in any of the following areas: sleep medicine, neurophysiology testing, neuro-rehabilitation, pain, or neuro-intensive care. Excellent medical community with all of the supportive consultants and technology. Send CV to: Neurological Associates of Grand Rapids, PC, 2855 Michigan Street, Northeast, Grand Rapids, MI 49506.

CHARLOTTE, NORTH CAROLINA: High quality group of six neurologists, all of whom are subspecialized, seeks to add a well-trained specialist. Contact: Mike Kaufman, MD, 126 Cottage Place, Charlotte, NC 28207. Or call: (704) 334-7311.

SOUTHEAST COAST — The Neuroscience Center of a 190-bed regional medical center is seeking a BC/BE neurologist to join in close association with their existing neurosurgeons. Exceptional medical facilities and neurological services including EEG/EMG, EP, CT, MRI. Excellent income guarantee plus benefits — large drawing area provides for outstanding potential. Located ninety minutes from one of this country's premiere seaside resorts, this dynamic community offers a quality lifestyle. Call Mark Prosperi at (800) 776-5776 for more details or send CV to: Cejka & Co., 1034 South Brentwood Boulevard, St. Louis, MO 63117.

PLEASE NOTE—Address replies to box number ads as follows: Box number, ______, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

Professional Opportunities

EXPANDING, DYNAMIC ADULT neurology practice — BC/BE neurologist to join rapidly growing office and multi-hospital practice in New Jersey — 15 minutes from Manhattan. Candidate must be energetic and personable. EMG, EEG experience preferred. Send CV to: Joseph Sobelman, MD, 834 Avenue C, Bayonne, NJ 07002.

NEUROLOGIST

Neurologist, board-eligible or board-certified, with EEG, EMG, EP and neuro-CT needed to join an adult neurologist in a 32-physician multi-specialty clinic, 100 miles southeast of St. Louis. Population 28,000 plus 25,000 Southern Illinois University students.

Opportunity exists for affiliation with SIU Medical School. No capital investment. Flexible compensation package with generous fringe benefits including health and disability, vacation, CME leave, and profit sharing retirement plan.

Contact:
William R. Hamilton,
CEO/Medical Director

CARBONDALE CLINIC
2601 West Main
Carbondale, IL 62901 ◆ (618) 549-5361

FLORIDA'S CENTRAL EAST COAST—Adult neurologist with EMG training wanted to join group of eight neurologists. We live an a high tech, beachside community with great schools and affordable housing. Please send CV to: Search Committee, P.O. Box 693, Melbourne, FL 32902.

Geisinger Medical Center

This 577-bed medical center, located in Danville, Pennsylvania, is the largest rural tertiary referral center in the country. The 275 full-time professional staff represents 63 specialties, and are supported by basic and clinical research and 16 accredited residency programs.

NEUROLOGY

The Geisinger Clinic seeks three superior candidates to join eleven adult neurologists, three pediatric neurologists, and a full-time neuropsychologist. Candidates possessing skills in general neurology, neuro-epileptology, or neuroimmunology are preferred. These unique positions offer opportunity for clinical, teaching, and research activities. Candidates must possess excellent clinical skills and be board certified/eligible in neurology. A comprehensive neurophysiology lab provides support in EEG, EMG, evoked response, transcranial Doppler, and ocular motor vestibular testing. Additional on-site support includes three CT scanners and two MRIs.

Geisinger offers an excellent compensation package and a family-oriented lifestyle and easy access to New York City, Philadelphia, Pittsburgh, and Washington, D.C. Applicants should send CV to: **Anthony P. Turel, M.D., Director, Department of Neurology, Geisinger Medical Center, Danville, Pennsylvania 17822-1405.** Equal Opportunity Employer M/F/H/V.

Geisinger

WANTED: NEUROLOGIST

New Orleans, Louisiana

Well established neurology group in west New Orleans suburb, seeking recently trained, board-certified or board-admissable neurologist to join a very busy practice of clinical and hospital adult neurology.

Competitive salary and early partnership, in a superb practice setting with a pleasant lifestyle.

Send curriculum vitae to:

Dennis Bottomley
Physician Placement Service of America
330 Franklin Road
Box 897
Brentwood, TN 37024
Or call: (800) 359-7421
FAX: (615) 395-4764

Professional Opportunities

EXCELLENT OPPORTUNITY for BC/BE neurologist to join 80-physician comprehensive, multi-specialty group in San Francisco Bay Area. Large, varied referral base from pediatrics, IM, FP, and surgery. EMG/NCV, EEG, Evoked Response Testing, CT, MRI, Radiology support all available on site. Opportunity to interface with specialists of all types including neurosurgeons. Major university teaching affiliation encouraged and possible. Close proximity to 400-bed full service, modern hospital serving population of 300,000. Competitive guaranteed salary with bonus productivity plan for initial 18 months leading to partnership track. Extensive benefit package including housing incentives. Unique cultural, recreational and educational opportunities. Send CV to: Gary D. Zweig, MD, Recruitment Chairman, Sunnyvale Medical Clinic, P.O. Box 3496, Sunnyvale, CA 94088-3496.

SOUTHEAST COAST — Pediatric Neurologist: Excellent quality of life available in Savannah-Hilton Head Area, site of the 1996 Olympic Games sailing events. Outstanding recreational opportunities, nation's largest urban Historic District, and superb symphony are among the attractions of living here. A well-trained, personable neurologist with special competence in child neurology is needed for a busy practice, currently consisting of two adult neurologists and one neurologist doing adult and child neurology, all with strong academic backgrounds. CT, EEG, EMG and physical therapy are available in-office with large hospital practice available in three hospitals, including a major regional teaching hospital, affiliated with the Medical College of Georgia. First year guarantee is $80,000 plus bonus, leading to full partnership after two years. Earnings potential, availability of strong multi-specialty support, and opportunities for teaching are extraordinary. If interested contact: Randy Wellman, Office Manager, Savannah Neurological Associates, PC, P.O. Box 23059, Savannah, GA 31403. (912) 354-8151.

— OHIO —

Very successful neurology group is seeking their third neurologist. Office conveniently located on the campus of a modern hospital located in a rapidly expanding suburb. This progressive city with its medical school and state university is an ideal place to satisfy both personal and professional needs. To learn more about this attractive opportunity we encourage you to call Barbara Lakoski at 1-800-243-4353 or send your CV to:

STRELCHECK & ASSOCIATES, INC.
12724 N. Maplecrest Lane
Mequon, WI 53092

ADULT NEUROLOGIST to associate with two separate, busy solo neurologists. Practices are referral based, with two separate offices and three voluntary hospitals. Successful candidate would be expected to develop a separate solo, but collaborative practice. Established physicians would expect to provide substantial support for beginning physician. Opportunity would provide for cross coverage and joint venturing of facilities. Successful candidate should have excellent clinical skills. The medical community has excellent neurophysiology, neuroradiology, and neurosurgery. Located in a medium size city with both excellent living conditions and an extremely solid economic base. Please contact: Jeffrey A. Ribner, MD, 503 Plaza Drive, Vestal, NY 13850. (607) 729-1521 or Robert R. Taylor, Jr., MD, 269 Riverside Drive, Johnson City, NY 13790. (607) 798-7143.

DENVER — Extremely busy, five-physician group with three Denver area offices are now seeking their fourth neurologist. Two members are neurosurgeons. Send CV to: Gordon Crawford, Manager, Professional Relations, Humana Inc., Department AN-4, 500 West Main Street, Louisville, KY 40201-1438. Or call toll-free (800) 626-1590.

PLEASE NOTE—Address replies to box number ads as follows: Box number, ________, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

Positions Available

SOUTHERN COLORADO: Exceptional practice and area. Opportunity to work with highly respected neurologist within a multi-specialty group. Practice to include: adult neurology, EEG, EMG, evoked potentials, CT and MRI. This vibrant community of 150,000 is located along the front range of the beautiful Rocky Mountains providing for a lifestyle second to none. Highly competitive first year income plus comprehensive benefits and relocation followed by partnership offering. For further details reply to: Wendy Perlman, 7385 Galloway Road, Miami, FL 33173. Or call: (800) 327-1585.

Positions Wanted

COMPHEALTH provides the finest locum tenens (temporary physician staffing) service nationwide. Each CompHealth neurologist is carefully screened and referenced ensuring you competent, reliable coverage. Have your practice covered or join us and cover other practices. Call CompHealth, the nation's oldest and largest supplier of temporary physician staffing services at: (800) 328-3043 toll-free: in Utah (801) 264-6400. Or write: 4021 South 700 East, Salt Lake City, UT 84107.

Faculty Positions

FACULTY POSITION — Available at Winthrop-University Hospital, a 548-bed major teaching affiliate of SUNY Stony Brook School of Medicine. Candidate should demonstrate excellence in patient care, teaching and research, as well as have an interest in pursuing a limited private practice. Expertise in EMG is desirable. Applicants should be board-certified/board-eligible. Interested applicants should send their curriculum vitae to: Malcolm H. Gottesman, MD, Acting Chief of Neurology, Winthrop-University Hospital, Division of Neurology, 222 Station Plaza North, Suite 438, Mineola, NY 11501. EOE. M/F/H/V.

CHIEF PEDIATRIC NEUROLOGY: A faculty position is available as Chief of the Division of Pediatric Neurology at the Nemours Children's Clinic. We are seeking an individual who is board-certified in pediatric neurology. In addition to direct patient care responsibility, the position offers academic appointment with the University of Florida at the level of Associate Professor/Professor. Guaranteed salary will be commensurate with applicant's experience. Please send CV to: Stephen Commins, MD, Chairman, Search Committee, Nemours Children's Clinic 807 Nira Street, Jacksonville, FL 32207. Academic status is offered by the University of Florida, an equal opportunity/affirmative action employer with whom Nemours is affiliated. Recruiting deadline: May 1, 1991.

ASSISTANT/ASSOCIATE PROFESSOR position — The Department of Neurology at the University of Minnesota Medical School has an opening for a tenure track Assistant/Associate Professor with subspecialty expertise in peripheral nerve and neuromuscular disease and in clinical electrophysiology. The candidate must have an MD, demonstrated ability to carry out peer-review funded independent research, and board-eligible in Neurology. The candidate will develop clinical care, training, and research programs in peripheral nerve disorders. Background should include fellowship in neuromuscular disease, training and board-eligibility/-certification in clinical neurophysiology with capability of directing a clinical laboratory, and a record of high-quality original publicaitons in peer-reviewed journals, etc. To be considered at the Associate Professor level, the candidate must show professional distinction in research and writing and demonstrated effectiveness in teaching and advising. This Assistant/Associate Professor will serve as an attending physician on the Neurology service and will participate in the teaching of residents, undergraduate, and graduate students. Applicants should send a CV by May 31, 1991 to: Richard W. Price, MD, Professor and Head, Deprtment of Neurology, Box 295, UMHC, Harvard Street at East River Road, Minneapolis, MN 55455. The University of Minnesota is an equal opportunity employer and specifically invites and encourages applications from women and minorities.

Neurologist

The Mason City Clinic
is a progressive
multi-specialty clinic in
the Heartland.

We are looking for a neurologist to join our very busy practice. Small-town security within two hours of Minneappolis and Des Moines.

MRI, CT, sleep lab, EEG, EMG, neurosurgery, cardiac surgery, orthopedic surgery, cancer center, GI lab, and ENT capabilities.

Excellent salary
and benefits.

Submit CV to:

Ralph A. Wolf, Administrator
300 N. Eisenhower Avenue
Mason City, IA 50401
(515) 423-2435

IMMEDIATE OPENING FOR A

GENERAL NEUROLOGIST

Private practice opportunity available immediately in east Tennessee with a well established neurologic practice.

Candidate should be BE/BC with competence in EEG, EMG and evoked potentials. Compensation individually negotiable. Excellent benefits also included. There is a wide variety of recreational facilities also available in the area.

Please submit CV to:

EAST
TENNESSEE
NEUROLOGY
CLINIC
Suite 501
Baptist Professional
Building
Knoxville, TN 37920

MADISON, WISCONSIN

Dean Medical Center, a 225-physician multi-specialty group is actively seeking an additional neurosurgeon to join the Neurosciences Department. The Neurosciences Department consists of three neurosurgeons, six neurologists and one neuropsychologist.

The neurosurgeons currently have a large volume of surgery cases (only 10% trauma) at St. Marys Hospital, a 340-bed facility located five blocks from the clinic. Ideal candidate should have interest in general and vascular neurosurgery, and desire a long term commitment to Dean Medical Center. All candidates must be board-eligible with goals to become board-certified.

Competitive salary and benefits provided with this position. For more information, send CV to or contact:

Scott M. Lindblom
Dean Medical Center
1313 Fish Hatchery Road
Madison, WI 53715

Work: (608) 252-8022
or
Home: (608) 276-8989

Faculty Positions

LOYOLA UNIVERSITY Chicago Stritch School of Medicine, Department of Neurology invites applications for two positions at the assistant professor level. Applicants should be board-eligible or -certified in neurology and have subspecialty expertise in either epilepsy, movement disorders, cerebrovascular or neuromuscular diseases. Preference will be given to candidates with clinical research interests. Send CV to: Gastone Celesia, MD, Chairman, Neurology Department, Loyola University Chicago, 2160 South First Avenue, Chicago, IL 60153. Loyola University Chicago is an equal opportunity/affirmative action employer.

Fellowships

CEREBROVASCULAR FELLOWSHIP available in Department of Neurology at the University of New Mexico. Individual will participate in clinical drug trials and research involving spect ¹H-NMR spectroscopy, MRI angiography and magnetoencephalography. Contact: Gary Rosenberg, MD, University of New Mexico Medical Center, Department of Neurology, Albuquerque, NM 87131-5281. (505) 277-3342. EEO.

Residencies

NEUROLOGY RESIDENCY PGY-2 position Stanford University — An unexpected neurology residency position is available starting July, 1991 at Stanford University Medical Center. For further information, contact: Dr. Gregory W. Albers, Director, Residency Training Program, Department of Neurology and Neurological Sciences, Stanford University Medical Center, Stanford, CA 94305. Equal opportunity employer.

SECOND YEAR NEUROLOGY RESIDENCY — Opening July 1991 for PGY3 resident in Georgetown University Program. Send CV to: Jonathan H. Pincus, MD, Professor and Chairman, Georgetown University Hospital, Department of Neurology, 1 Bles Building, 3800 Reservoir Road, NW, Washington, DC 20007. (202) 784-2170. EOE.

Residencies

THE UNIVERSITY OF CHICAGO Neurology Department is offering a second year neurology residency position (PGY 3) beginning July 1991. For information contact: Richard P. Kraig, PhD, MD, Residency Director, Department of Neurology, University of Chicago Medical Center, 5841 South Maryland, BH - Box 425, Chicago, IL 60637. (312) 702-0151.

THE UNIVERSITY OF CINCINNATI Neurology Department is offering a second year neurology residency position (PGY3) beginning as soon as possible. For information contact: Joseph P. Broderick, MD, Residency Director, Department of Neurology, University of Cincinnati Medical Center, Cincinnati, OH 45267-0525. (513) 558-5431.

Medical Equipment/Supplies

SOLO PHYSICIAN joining group has used equipment in good condition for sale; Nicolet Evoked Potential, EMG, Oxford Ambulatory EEG (scanner, recorder, sleep stages), Biosound Carotid Ultrasound Imager. Contact: Paul Bustion, MD, 1801 North Senate Boulevard, Suite 510, Indianapolis, IN 46202. (317) 929-5828.

FOR SALE — BIOLOGIC III

20 channel EEG/VER; color jet printer; 80286 16 bit microprocessor. 5¼" dbl/dbl floppy with 1.2 MEG storage; 20 MEG hard disk; RGB 13" CRT. Cart, banker. $50,000 OBO.

Contact Barbara Jessen: (206) 242-0201.

1985 NIHON KOHDEN Neuropack 8 Evoked Potential Machine-VEP, BAEP, SSEP; with color monitor and plotter. Excellent condition: $15,000. (703) 885-6000.

Cognitive Neuroscience Fellowships

offered by the

Cognitive Neuroscience Section • Medical Neurology Branch

National Institute of Neurological Disorders and Stroke
National Institutes of Health • Public Health Service

Starting Date: Summer or Fall, 1991

We are seeking psychologists with a strong interest in either memory and amnesia, reasoning and problem solving, social cognition or cognitive event-related potentials. Exceptional candidates with other areas of interest will be considered. The Research Fellow positions will be in the Cognitive Neuroscience Section of the Medical Neurology Branch, NINDS, NIH. The Cognitive Neuroscience Section conducts research in the following areas: *Memory and Amnesia, Neurolinguistics and Aphasia, Visual Attention, Perception and Agnosia, Cognitive Psychophysiology, Frontal Lobe Functions, and Knowledge Representation* using cognitive science, neuropsychological and evoked-response techniques. A variety of normal control and patient populations are being studied including Stroke, Parkinson's Disease, Cerebellar lesions, Alzheimer's Disease, Encephalitis, Demyelinating Disorders, HIV Dementia, Brain Tumors, Head Injury, Multiple Personality Disorder, Chronic Fatigue Syndrome, Dystonia, and Progressive Supranuclear Palsy. The ability to conduct original research, as well as engage in collaborative research, is required. Candidates trained in cognitive science/psychology programs are encouraged to apply.

The Cognitive Neuroscience Fellowships *include* tutorial training in neurobehavioral assessment and diagnostics, participation in clinical rounds, development of research projects, and seminar presentations. The training program is oriented towards developing skills and credentials for a career in cognitive neuropsychology. As a Research Fellow, your salary will range from $24,000 to $40,345 depending on experience and qualifications. Travel expenses and Federal health care benefits are available.

For further information, please contact:

Jordan Grafman, Ph.D., Chief
Cognitive Neuroscience Section
Medical Neurology Branch
NINDS, NIH
Building 10, Room 5C422
9000 Rockville Pike
Bethesda, Maryland 20892
(Phone: 301-496-0220)

Interested candidates should send a vitae, statement of research interests, representative reprints or pre-prints, and three letters of recommendation to Dr. Grafman. For further information and qualification requirements contact **Glenn Hartzoge, NINDS Personnel Office, (301) 496-6334.**

NIH IS AN EQUAL OPPORTUNITY EMPLOYER

Behavioral Neurology Fellowship

offered by the

Cognitive Neuroscience Section • Medical Neurology Branch

National Institute of Neurological Disorders and Stroke

National Institutes of Health • Public Health Service

Starting Date: July 1, 1991

We are awarding a Behavioral Neurology Fellowship beginning July, 1991. We are seeking a Board Certified or eligible neurologist with a strong research interest in the brain mechanisms underlying cognitive functioning. The Clinical Associate position will be in the Cognitive Neuroscience Section of the Medical Neurology Branch, NINDS, NIH. The Cognitive Neuroscience Section conducts research in the following areas: *Memory and Amnesia, Neurolinguistics and Aphasia, Visual Attention, Perception and Agnosia, Cognitive Psychophysiology, Frontal Lobe Functions, and Knowledge Representation* using neuropsychological and evoked-response techniques. A variety of patient populations are studied including Stroke, Parkinson's Disease, Cerebellar lesions, Alzheimer's Disease, Encephalitis, Demyelinating Disorders, HIV Dementia, Brain Tumors, Head Injury, Multiple Personality Disorder, Chronic Fatigue Syndrome, Dystonia, and Progressive Supranuclear Palsy. The initiation of experimental pharmacological intervention studies in patients suffering from memory impairment is encouraged.

The Behavioral Neurology Fellowship *includes* tutorial training in neurobehavioral assessment and diagnostics, participation in clinical rounds, development of research projects, and seminar presentations. The training program is oriented towards developing skills and credentials for a career in academic neurology. Clinical Associates receive an initial salary of $37,000 a year. Moving expenses, travel expenses and Federal health care benefits are available.

SANDOZPHARMACEUTICALS
Corporation, E. Hanover, NJ 07936 (201) 503-7500

C-CAF-0689-01
© 1991 Sandoz Pharmaceuticals Corporation

Cafergot®

(ergotamine tartrate and caffeine) tablets, USP
(ergotamine tartrate and caffeine) suppositories, USP

DESCRIPTION

Cafergot® (ergotamine tartrate and caffeine) Tablet

ergotamine tartrate USP .... 1 mg
caffeine USP .... 100 mg

Inactive Ingredients: acacia, carnauba wax, lactose, methylparaben, povidone, propylparaben, sodium benzoate, sorbitol, starch, stearic acid, sucrose, synthetic black ferric oxide, synthetic red ferric oxide, synthetic yellow ferric oxide, talc, tartaric acid, and titanium dioxide.

Cafergot® (ergotamine tartrate and caffeine) Suppository

ergotamine tartrate USP .... 2 mg
caffeine USP .... 100 mg

Inactive Ingredients: cocoa butter NF and tartaric acid NF.

Cafergot® (ergotamine tartrate and caffeine) suppositories are *sealed* in foil to afford protection from cocoa butter leakage. If an unavoidable period of exposure to heat softens the suppository, it should be chilled in ice-cold water to solidify it before removing the foil.

ACTIONS: Ergotamine is an alpha adrenergic blocking agent with a direct stimulating effect on the smooth muscle of peripheral and cranial blood vessels and produces depression of central vasomotor centers. The compound also has the properties of serotonin antagonism. In comparison to hydrogenated ergotamine, the adrenergic blocking actions are less pronounced and vasoconstrictive actions are greater.

Caffeine, also a cranial vasoconstrictor, is added to further enhance the vasoconstrictive effect without the necessity of increasing ergotamine dosage.

Many migraine patients experience excessive nausea and vomiting during attacks, making it impossible for them to retain any oral medication. In such cases, therefore, the only practical means of medication is through the rectal route where medication may reach the cranial vessels directly, evading the splanchnic vasculature and the liver.

INDICATIONS

Cafergot® (ergotamine tartrate and caffeine)

Indicated as therapy to abort or prevent vascular headache, e.g., migraine, migraine variants or so-called "histaminic cephalalgia".

CONTRAINDICATIONS: Peripheral vascular disease, coronary heart disease, hypertension, impaired hepatic or renal function, sepsis and pregnancy.

Hypersensitivity to any of the components.

PRECAUTIONS: Although signs and symptoms of ergotism rarely develop even after long term intermittent use of the orally or rectally administered drugs, care should be exercised to remain within the limits of recommended dosage.

Ergotism is manifested by intense arterial vasoconstriction, producing signs and symptoms of peripheral vascular ischemia. Ergotamine induces vasoconstriction by a direct action on vascular smooth muscle. In chronic intoxication with ergot derivatives, headache, intermittent claudication, muscle pains, numbness, coldness and pallor of the digits may occur. If the condition is allowed to progress untreated, gangrene can result.

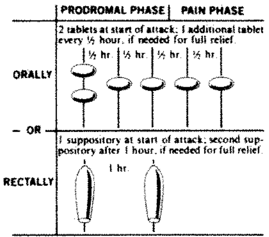
While most cases of ergotism associated with ergotamine treatment result from frank overdosage, some cases have involved apparent hypersensitivity. There are few reports of ergotism among patients taking doses within the recommended limits or for brief periods of time. In rare instances, patients, particularly those who have used the medication indiscriminately over long periods of time, may display withdrawal symptoms consisting of rebound headache upon discontinuation of the drug.

There have been reports of drug abuse and psychological dependence in patients on Cafergot® (ergotamine tartrate and caffeine) therapy. Due to the chronicity of vascular headaches, it is imperative that patients be advised not to exceed recommended dosages with long-term use to avoid ergotism.

ADVERSE REACTIONS: Vasoconstrictive complications, at times of a serious nature, may occur. These include pulselessness, weakness, muscle pains and paresthesias of the extremities and precordial distress and pain. Although these effects occur most commonly with long-term therapy at relatively high doses, they have also been reported with short-term or normal doses. Other adverse effects include transient tachycardia or bradycardia, nausea, vomiting, localized edema and itching.

DOSAGE AND ADMINISTRATION

Procedure: For the best results, dosage should start at the first sign of an attack.



PRODROMAL PHASE
PAIN PHASE
2 tablets at start of attack; 1 additional tablet every ½ hour, if needed for full relief.
½ hr.
½ hr.
½ hr.
½ hr.
ORALLY
— OR —
1 suppository at start of attack; second suppository after 1 hour, if needed for full relief.
1 hr.
RECTALLY

Early Administration Gives Maximum Effectiveness

MAXIMUM ADULT DOSAGE

Orally: Total dose for any one attack should not exceed 6 tablets.

Rectally: Two suppositories is the maximum dose for an individual attack.

Total weekly dosage should not exceed 10 tablets or 5 suppositories.

In carefully selected patients, with due consideration of maximum dosage recommendations, administration of the drug at bedtime may be an appropriate short-term preventive measure.

OVERDOSAGE: The toxic effects of an acute overdosage of Cafergot® (ergotamine tartrate and caffeine) are due primarily to the ergotamine component. The amount of caffeine is such that its toxic effects will be overshadowed by those of ergotamine. Symptoms include vomiting, numbness, tingling, pain and cyanosis of the extremities associated with diminished or absent peripheral pulses; hypertension or hypotension; drowsiness, stupor, coma, convulsions and shock. A case has been reported of reversible bilateral papillitis with ring scotomata in a patient who received five times the recommended daily adult dose over a period of 14 days.

Treatment consists of removal of the offending drug by induction of emesis, gastric lavage, and catharsis. Maintenance of adequate pulmonary ventilation, correction of hypotension, and control of convulsions are important considerations. Treatment of peripheral vasospasm should consist of warmth, but not heat, and protection of the ischemic limbs. Vasodilators may be used with benefit but caution must be exercised to avoid aggravating an already existent hypotension.

HOW SUPPLIED

Cafergot® (ergotamine tartrate and caffeine) Tablets

Shell pink colored, sugar coated, imprinted "CAFERGOT" on one side, "S" on other side. Bottles of 250, NDC 0078-0034-28, and cartons of three SigPak® (dispensing unit) packages, each containing 30 tablets in individual blisters, NDC 0078-0034-42.

Cafergot® (ergotamine tartrate and caffeine) Suppositories

Sealed in fuchsia-colored aluminum foil, imprinted "S CAFERGOT® SUPPOSITORY 78-33 SANDOZ". Boxes of 12, NDC 0078-0033-02.

Dilantin® KAPSEALS® (Extended Phenytoin Sodium Capsules, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows.

INDICATIONS AND USAGE: Dilantin is indicated for the control of generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and prevention and treatment of seizures occurring during or following neurosurgery.

Phenytoin serum level determinations may be necessary for optimal dosage adjustments (see Dosage and Administration and Clinical Pharmacology in the full prescribing information).

CONTRAINDICATIONS: Phenytoin is contraindicated in those patients who are hypersensitive to phenytoin or other hydantoins.

WARNINGS: Abrupt withdrawal of phenytoin in epileptic patients may precipitate status epilepticus. When, in the judgment of the clinician, the need for dosage reduction, discontinuation, or substitution of alternative antiepileptic medication arises, this should be done gradually. However, in the event of an allergic or hypersensitivity reaction, rapid substitution of alternative therapy may be necessary. In this case, alternative therapy should be an antiepileptic drug not belonging to the hydantoin chemical class.

There have been a number of reports suggesting a relationship between phenytoin and the development of lymphadenopathy (local or generalized) including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin's Disease. Although a cause and effect relationship has not been established, the occurrence of lymphadenopathy indicates the need to differentiate such a condition from other types of lymph node pathology. Lymph node involvement may occur with or without symptoms and signs resembling serum sickness, eg, fever, rash and liver involvement.

In all cases of lymphadenopathy, follow-up observation for an extended period is indicated and every effort should be made to achieve seizure control using alternative antiepileptic drugs.

Acute alcoholic intake may increase phenytoin serum levels while chronic alcoholic use may decrease serum levels.

In view of isolated reports associating phenytoin with exacerbation of porphyria, caution should be exercised in using this medication in patients suffering from this disease.

Usage in Pregnancy: A number of reports suggests an association between the use of antiepileptic drugs by women with epilepsy and a higher incidence of birth defects in children born to these women. Data are more extensive with respect to phenytoin and phenobarbital, but these are also the most commonly prescribed antiepileptic drugs; less systematic or anecdotal reports suggest a possible similar association with the use of all known antiepileptic drugs.

Dilantin® Kapseals®

(extended phenytoin sodium capsules, USP)

The reports suggesting a higher incidence of birth defects in children of drug-treated epileptic women cannot be regarded as adequate to prove a definite cause and effect relationship. There are intrinsic methodological problems in obtaining adequate data on drug teratogenicity in humans; genetic factors or the epileptic condition itself may be more important than drug therapy in leading to birth defects. The great majority of mothers on antiepileptic medication deliver normal infants. It is important to note that antiepileptic drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures, because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus. The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

In addition to the reports of increased incidence of congenital malformation, such as cleft lip/palate and heart malformations, in children of women receiving phenytoin and other antiepileptic drugs, there have more recently been reports of a fetal hydantoin syndrome. This consists of prenatal growth deficiency, microcephaly and mental deficiency in children born to mothers who have received phenytoin, barbiturates, alcohol, or trimethadione. However, these features are all interrelated and are frequently associated with intrauterine growth retardation from other causes.

There have been isolated reports of malignancies, including neuroblastoma, in children whose mothers received phenytoin during pregnancy.

An increase in seizure frequency during pregnancy occurs in a high proportion of patients, because of altered phenytoin absorption or metabolism. Periodic measurement of serum phenytoin levels is particularly valuable in the management of a pregnant epileptic patient as a guide to an appropriate adjustment of dosage. However, postpartum restoration of the original dosage will probably be indicated.

Neonatal coagulation defects have been reported within the first 24 hours in babies born to epileptic mothers receiving phenobarbital and/or phenytoin. Vitamin K has been shown to prevent or correct this defect and has been recommended to be given to the mother before delivery and to the neonate after birth.

PRECAUTIONS: General: The liver is the chief site of biotransformation of phenytoin; patients with impaired liver function, elderly patients, or those who are gravely ill may show early signs of toxicity.

A small percentage of individuals who have been treated with phenytoin has been shown to metabolize the drug slowly. Slow metabolism may be due to limited enzyme availability and lack of induction; it appears to be genetically determined.

Phenytoin should be discontinued if a skin rash appears (see "Warnings" section regarding drug discontinuation). If the rash is exfoliative, purpuric, or bullous or if lupus erythematosus, Stevens-Johnson syndrome, or toxic epidermal necrolysis is suspected, use of this drug should not be resumed and alternative therapy should be considered. (See Adverse Reactions.) If the rash is of a milder type (measles-like or scarlatiniform), therapy may be resumed after the rash has completely disappeared. If the rash recurs upon reinstitution of therapy, further phenytoin medication is contraindicated.

Phenytoin and other hydantoins are contraindicated in patients who have experienced phenytoin hypersensitivity. Additionally, caution should be exercised if using structurally similar (eg, barbiturates, succinimides, oxazolidinediones and other related compounds) in these same patients.

Hyperglycemia, resulting from the drug's inhibitory effects on insulin release, has been reported. Phenytoin may also raise the serum glucose level in diabetic patients.

Osteomalacia has been associated with phenytoin therapy and is considered to be due to phenytoin's interference with Vitamin D metabolism.

Phenytoin is not indicated for seizures due to hypoglycemic or other metabolic causes. Appropriate diagnostic procedures should be performed as indicated.

Phenytoin is not effective for absence (petit mal) seizures. If tonic-clonic (grand mal) and absence (petit mal) seizures are present, combined drug therapy is needed.

Serum levels of phenytoin sustained above the optimal range may produce confusional states referred to as "delirium," "psychosis," or "encephalopathy," or rarely irreversible cerebellar dysfunction. Accordingly, at the first sign of acute toxicity, plasma levels are recommended. Dose reduction of phenytoin therapy is indicated if plasma levels are excessive; if symptoms persist, termination is recommended. (See Warnings.)

Information for Patients: Patients taking phenytoin should be advised of the importance of adhering strictly to the prescribed dosage regimen, and of informing the physician of any clinical condition in which it is not possible to take the drug orally as prescribed, eg, surgery, etc.

Patients should also be cautioned on the use of other drugs or alcoholic beverages without first seeking the physician's advice.

Patients should be instructed to call their physician if skin rash develops.

The importance of good dental hygiene should be stressed in order to minimize the development of gingival hyperplasia and its complications.

Do not use capsules which are discolored.

Laboratory Tests: Phenytoin serum level determinations may be necessary to achieve optimal dosage adjustments.

Drug Interactions: There are many drugs which may increase or decrease phenytoin levels or which phenytoin may affect. Serum level determinations for phenytoin are especially helpful when possible drug interactions are suspected. The most commonly occurring drug interactions are listed below: 1. Drugs which may increase phenytoin serum levels include: acute alcohol intake, amiodarone, chloramphenicol, chlordiazepoxide, diazepam, dicumarol, disulfiram, estrogens, H_2-antagonists, halothane, isoniazid, methylphenidate, phenothiazines, phenylbutazone, salicylates, succinimides, sulfonamides, tolbutamide, trazodone.

2. Drugs which may decrease phenytoin levels include: carbamazepine, chronic alcohol abuse, reserpine, and sucralfate. Moban® brand of molindone hydrochloride contains calcium ions which interfere with the absorption of phenytoin. Ingestion times of phenytoin and antacid preparations containing calcium should be staggered in patients with low serum phenytoin levels to prevent absorption problems.

3. Drugs which may either increase or decrease phenytoin serum levels include: phenobarbital, sodium valproate, and valproic acid. Similarly, the effect of phenytoin on phenobarbital, valproic acid and sodium valproate serum levels is unpredictable.

4. Although not a true drug interaction, tricyclic antidepressants may precipitate seizures in susceptible patients and phenytoin dosage may need to be adjusted.

5. Drugs whose efficacy is impaired by phenytoin include: corticosteroids, coumarin anticoagulants, digitoxin, doxycycline, estrogens, furosemide, oral contraceptives, quinidine, rifampin, theophylline, vitamin D.

Drug/Laboratory Test Interactions: Phenytoin may cause decreased serum levels of protein-bound iodine (PBI). It may also produce lower than normal values for dexamethasone or metyrapone tests. Phenytoin may cause increased serum levels of glucose, alkaline phosphatase, and gamma glutamyl transpeptidase (GGT).

Carcinogenesis: See "Warnings" section for information on carcinogenesis.

Pregnancy: See Warnings.

Nursing Mothers: Infant breast-feeding is not recommended for women taking this drug because phenytoin appears to be secreted in low concentrations in human milk.

ADVERSE REACTIONS: Central Nervous System: The most common manifestations encountered with phenytoin therapy are referable to this system and are usually dose-related. These include nystagmus, ataxia, slurred speech, decreased coordination and mental confusion. Dizziness, insomnia, transient nervousness, motor twitchings, and headaches have also been observed. There have also been rare reports of phenytoin induced dyskinesias, including chorea, dystonia, tremor and asterixis, similar to those induced by phenothiazine and other neuroleptic drugs.

A predominantly sensory peripheral polyneuropathy has been observed in patients receiving long-term phenytoin therapy.

Gastrointestinal System: Nausea, vomiting, constipation, toxic hepatitis and liver damage.

Integumentary System: Dermatological manifestations sometimes accompanied by fever have included scarlatiniform or morbilliform rashes. A morbilliform rash (measles-like) is the most common; other types of dermatitis are seen more rarely. Other more serious forms which may be fatal have included bullous, exfoliative or purpuric dermatitis, lupus erythematosus, Stevens-Johnson syndrome, and toxic epidermal necrolysis (see Precautions).

Hemopoietic System: Hemopoietic complications, some fatal, have occasionally been reported in association with administration of phenytoin. These have included thrombocytopenia, leukopenia, granulocytopenia, agranulocytosis, and pancytopenia with or without bone marrow suppression. While macrocytosis and megaloblastic anemia have occurred, these conditions usually respond to folic acid therapy. Lymphadenopathy including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin's Disease have been reported (see Warnings).

Connective Tissue System: Coarsening of the facial features, enlargement of the lips, gingival hyperplasia, hypertrichosis and Peyronie's Disease.

Cardiovascular: Periarteritis nodosa.

Immunologic: Hypersensitivity syndrome (which may include, but is not limited to, symptoms such as arthralgias, eosinophilia, fever, liver dysfunction, lymphadenopathy or rash), systemic lupus erythematosus, immunoglobulin abnormalities.

OVERDOSAGE: The lethal dose in children is not known. The lethal dose in adults is estimated to be 2 to 5 grams. The initial symptoms are nystagmus, ataxia, and dysarthria. Other signs are tremor, hyperreflexia, lethargy, slurred speech, nausea, vomiting. The patient may become comatose and hypotensive. Death is due to respiratory and circulatory depression.

There are marked variations among individuals with respect to phenytoin plasma levels where toxicity may occur. Nystagmus, on lateral gaze, usually appears at 20 mcg/mL, ataxia at 30 mcg/mL, dysarthria and lethargy appear when the plasma concentration is over 40 mcg/mL, but as high a concentration as 50 mcg/mL has been reported without evidence of toxicity. As much as 25 times the therapeutic dose has been taken to result in a serum concentration over 100 mcg/mL with complete recovery.

Treatment: Treatment is nonspecific since there is no known antidote.

The adequacy of the respiratory and circulatory systems should be carefully observed and appropriate supportive measures employed. Hemodialysis can be considered since phenytoin is not completely bound to plasma proteins. Total exchange transfusion has been used in the treatment of severe intoxication in children.

In acute overdosage the possibility of other CNS depressants, including alcohol, should be borne in mind.

Caution – Federal law prohibits dispensing without prescription. 0362G280

As rare as a seizure on Dilantin® (extended phenytoin sodium capsules, USP) 100 mg

For as many as 86% of patients, seizures occur only once in a blue moon—if at all—once Dilantin monotherapy is under way.[1]

That fact holds true for partial, complex partial, generalized tonic-clonic seizures, and status epilepticus.

And it's achieved *without* significant cognitive impairment at therapeutic drug levels (10 to 20 μg/mL),[2] often *with* once-daily therapy (Dilantin® Kapseals®), which enhances compliance.

What you demand, Dilantin does—for millions of patients every day.

That's why Dilantin remains a drug of choice.

And that's why most patients on Dilantin will wait a long, long time to see another seizure.

Dilantin®

"Once in a blue moon" describes the phenomenon in which the moon appears as a brilliant blue. Seen worldwide following the volcanic eruption of Krakatoa in 1883, the blue moon occurs only when atmospheric cloud droplets, each less than 5 μm in diameter, form in abundance—an exceedingly rare event.[3]

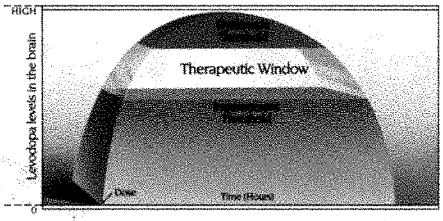
Sinemet®...for many patients with Parkinson's disease, the foundation of therapy for 15 years.

Sinemet®

(Carbidopa-Levodopa)

Power and Precision

Only Sinemet® provides the power to re-establish dopamine levels in the brain and the precision to adjust dosage to meet the individual needs of the patient.



Maintaining Dopamine Levels Within the Therapeutic Window*The aim of clinical intervention in Parkinson's disease is to maintain dopamine levels within a therapeutic window. The three dosage strengths of Sinemet® help meet this challenge by providing both the power to replenish dopamine levels in the brain and the precision to adjust to individual patient needs.*

Managing Parkinson's disease therapy can be complex. The critical need is to maintain dopamine levels in the brain within an ever-narrowing therapeutic window. A window that is different in every patient and one that changes over time because of the progressive nature of the disease.

Dopamine replacement is the mainstay of therapy in Parkinson's disease. And, only Sinemet® has the power to re-establish dopamine levels in the brain.

But, power alone is not enough. Sinemet® also provides you the flexibility to meet the individual needs of the patient...by changing dosage strength or frequency...or by changing the ratio of carbidopa and levodopa.

Nothing else gives you this power and precision to manage the signs and symptoms of Parkinson's disease like Sinemet®.

As with levodopa, SINEMET* may cause involuntary movements and mental disturbances. These reactions are thought to be due to increased brain dopamine levels following administration of levodopa.

Please see a brief summary of prescribing information on the adjoining page.

Sinemet®
(Carbidopa-Levodopa)

ONE OF A KIND

DU PONT
PHARMA

Du Pont Pharmaceuticals
Wilmington, DE 19880-0026

©1991 Du Pont Pharmaceuticals
*Sinemet is a registered trademark of Merck & Co., Inc.

For many patients with Parkinson's disease

Dosage Guidelines

*Individualized dosage—a key to clinical success with Sinemet**

- Begin when symptoms first interfere with normal function
- Adjust as necessary to help maintain relief of symptoms

1

For initial therapy...Start with:

SINEMET 25-100

containing 25 mg carbidopa (anhydrous equivalent) and 100 mg levodopa

one tablet t.i.d.

If necessary, to control symptoms, dosage may be increased by one tablet every day or every other day until a dosage of eight tablets of Sinemet 25-100 a day is reached.

2

When it is evident that patients need more levodopa...Transfer to:

SINEMET 25-250

containing 25 mg carbidopa (anhydrous equivalent) and 250 mg levodopa

one tablet t.i.d.

If still more levodopa is necessary, dosage with Sinemet 25-250 may be increased by one-half to one tablet every day or every other day to a maximum of eight tablets a day.

3

When individualizing dosage...Titrate with:

SINEMET 10-100

containing 10 mg carbidopa (anhydrous equivalent) and 100 mg levodopa

or SINEMET 25-100

or SINEMET 25-250

The optimum daily dosage of Sinemet must be determined by careful titration in each patient. Tablets of the three strengths may be given separately or combined as needed to provide the optimum daily dosage.

For patients transferred from levodopa

DISCONTINUE LEVODOPA AT LEAST 8 HOURS BEFORE STARTING SINEMET.

The starting dose for Sinemet should provide about 25 percent of previous levodopa requirements. (Patients receiving less than 1500 mg of levodopa a day should be started on one tablet of Sinemet 25-100 t.i.d. or q.i.d.)

Sinemet®
(Carbidopa-Levodopa)

When SINEMET is to be given to patients who are being treated with levodopa, levodopa must be discontinued at least 8 hours before therapy with SINEMET is started. In order to reduce adverse reactions, it is necessary to individualize therapy. See the WARNINGS (below) and DOSAGE AND ADMINISTRATION sections in the Prescribing Information before initiating therapy.

Contraindications: MAO inhibitors and SINEMET should not be given concomitantly. MAO inhibitors must be discontinued at least 2 weeks prior to initiating therapy with SINEMET.

SINEMET is contraindicated in patients with known hypersensitivity to this drug and in narrow-angle glaucoma.

Because levodopa may activate a malignant melanoma, it should not be used in patients with suspicious, undiagnosed skin lesions or history of melanoma.

Warnings: Levodopa must be discontinued at least 8 hours before SINEMET is started. SINEMET should be substituted at a dosage that will provide approximately 25 percent of the previous levodopa dosage. (See DOSAGE AND ADMINISTRATION section of Prescribing Information.) Patients taking SINEMET should be instructed not to take additional levodopa unless prescribed.

As with levodopa, SINEMET may cause involuntary movements and mental disturbances. These reactions may be due to increased brain dopamine following administration of levodopa. All patients should be observed carefully for development of depression with concomitant suicidal tendencies. Treat with caution patients with past or current psychoses. *Because carbidopa permits more levodopa to reach the brain and, thus, more dopamine to be formed, dyskinesias may occur at lower dosages and sooner with* SINEMET *than with levodopa*. Occurrence of dyskinesias may require dosage reduction.

SINEMET should be administered cautiously to patients with severe cardiovascular or pulmonary disease, bronchial asthma, renal, hepatic or endocrine disease.

Exercise care in administering SINEMET, as with levodopa, to patients with history of myocardial infarction who have residual atrial, nodal, or ventricular arrhythmias. In such patients, cardiac function should be monitored with particular care during period of initial dosage adjustment, in a facility with provisions for intensive cardiac care.

As with levodopa, there is possibility of upper GI hemorrhage in patients with history of peptic ulcer.

A symptom complex resembling the neuroleptic malignant syndrome including muscular rigidity, elevated body temperature, mental changes, and increased serum creatine phosphokinase has been reported when antiparkinsonian agents were withdrawn abruptly. Therefore, patients should be observed carefully when the dosage of SINEMET is reduced abruptly or discontinued, especially if the patient is receiving neuroleptics.

Usage in Pregnancy and Lactation: Although effects of SINEMET on human pregnancy and lactation are unknown, both levodopa and combinations of carbidopa and levodopa have caused visceral and skeletal malformations in rabbits. Use of SINEMET in women of childbearing potential requires that anticipated benefits of the drug be weighed against possible hazards to mother and child. SINEMET should not be given to nursing mothers.

Usage in Children: Safety of SINEMET in patients under 18 has not been established.

Precautions: As with levodopa, periodic evaluations of hepatic, hematopoietic, cardiovascular, and renal function are recommended during extended therapy.

Patients with chronic wide-angle glaucoma may be treated cautiously with SINEMET provided intraocular pressure is well controlled and patient is monitored carefully for changes in intraocular pressure during therapy.

Laboratory Tests: Abnormalities in laboratory tests may include elevations of liver function tests such as alkaline phosphatase, SGOT (AST), SGPT (ALT), lactic dehydrogenase, and bilirubin. Abnormalities in protein-bound iodine, blood urea nitrogen, and positive Coombs test have also been reported. Commonly, levels of blood urea nitrogen, creatinine, and uric acid are lower during administration of SINEMET than with levodopa.

SINEMET may cause a false-positive reaction for urinary ketone bodies when a test tape is used for determination of ketonuria. This reaction will not be altered by boiling the urine specimen. False-negative tests may result with the use of glucose-oxidase methods of testing for glucosuria.

Drug Interactions: Caution should be exercised when the following drugs are administered concomitantly with SINEMET.

Symptomatic postural hypotension can occur when SINEMET is added to the treatment of a patient receiving antihypertensive drugs. Therefore, when therapy with SINEMET is started, dosage adjustment of the antihypertensive drug may be required. For patients receiving monoamine oxidase inhibitors, see CONTRAINDICATIONS (above).

There have been rare reports of adverse reactions, including hypertension and dyskinesia, resulting from the concomitant use of tricyclic antidepressants and SINEMET.

Phenothiazines and butyrophenones may reduce the therapeutic effects of levodopa. In addition, the beneficial effects of levodopa in Parkinson's disease have been reported to be reversed by phenytoin and papaverine. Patients taking these drugs with SINEMET should be carefully observed for loss of therapeutic response.

Adverse Reactions: Most common serious adverse reactions occurring with SINEMET are choreiform, dystonic, and other involuntary movements. Other serious adverse reactions are mental changes including paranoid ideation and psychotic episodes, depression with or without development of suicidal tendencies and dementia. Convulsions also have occurred; however, a causal relationship with SINEMET has not been established.

A common but less serious effect is nausea.

Less frequent adverse reactions are cardiac irregularities and/or palpitation, orthostatic hypotensive episodes, bradykinetic episodes (the "on-off" phenomenon), anorexia, vomiting, and dizziness.

Rarely, GI bleeding, development of duodenal ulcer, hypertension, phlebitis, hemolytic and non-hemolytic anemia, thrombocytopenia, leukopenia, and agranulocytosis have occurred.

Laboratory tests which have been reported to be abnormal are alkaline phosphatase, SGOT (AST), SGPT (ALT), lactic dehydrogenase, bilirubin, blood urea nitrogen, protein-bound iodine, and Coombs test.

Other adverse reactions that have been reported with levodopa are: *Nervous System*: ataxia, numbness, increased hand tremor, muscle twitching, muscle cramps, blepharospasm (which may be taken as an early sign of excess dosage, consideration of dosage reduction may be made at this time), trismus, activation of latent Horner's syndrome. *Psychiatric*: confusion, sleepiness, insomnia, nightmares, hallucinations, delusions, agitation, anxiety, euphoria. *Gastrointestinal*: dry mouth, bitter taste, sialorrhea, dysphagia, bruxism, hiccups, abdominal pain and distress, constipation, diarrhea, flatulence, burning sensation of tongue. *Metabolic*: weight gain or loss, edema. *Integumentary*: malignant melanoma (see also CONTRAINDICATIONS), flushing, increased sweating, dark sweat, skin rash, loss of hair. *Genitourinary*: urinary retention, urinary incontinence, dark urine, priapism. *Special Senses*: diplopia, blurred vision, dilated pupils, oculogyric crises. *Miscellaneous*: weakness, faintness, fatigue, headache, hoarseness, malaise, hot flashes, sense of stimulation, bizarre breathing patterns, neuroleptic malignant syndrome.

Overdosage: Management of acute overdosage with SINEMET is basically the same as management of acute overdosage with levodopa; however, pyridoxine is not effective in reversing the actions of SINEMET.

How Supplied: Tablets SINEMET 10-100, SINEMET 25-100, and SINEMET 25-250 are supplied in bottles of 100 and unit dose packages of 100.

Storage: Tablets SINEMET 10-100 and Tablets SINEMET 25-250 must be protected from light.

SANDOZPHARMACEUTICALS
Corporation, E. Hanover, NJ 07936 (201) 503-7500

C-CAF-0689-01

© 1991 Sandoz Pharmaceuticals Corporation

Cafergot®

(ergotamine tartrate and caffeine) tablets, USP
(ergotamine tartrate and caffeine) suppositories, USP

DESCRIPTION

Cafergot® (ergotamine tartrate and caffeine) Tablet

ergotamine tartrate USP .... 1 mg
caffeine USP .... 100 mg

Inactive Ingredients: acacia, carnauba wax, lactose, methylparaben, povidone, propylparaben, sodium benzoate, sorbitol, starch, stearic acid, sucrose, synthetic black ferric oxide, synthetic red ferric oxide, synthetic yellow ferric oxide, talc, tartaric acid, and titanium dioxide.

Cafergot® (ergotamine tartrate and caffeine) Suppository

ergotamine tartrate USP .... 2 mg
caffeine USP .... 100 mg

Inactive Ingredients: cocoa butter NF and tartaric acid NF.

Cafergot® (ergotamine tartrate and caffeine) suppositories are *sealed* in foil to afford protection from cocoa butter leakage. If an unavoidable period of exposure to heat softens the suppository, it should be chilled in ice-cold water to solidify it before removing the foil.

ACTIONS: Ergotamine is an alpha adrenergic blocking agent with a direct stimulating effect on the smooth muscle of peripheral and cranial blood vessels and produces depression of central vasomotor centers. The compound also has the properties of serotonin antagonism. In comparison to hydrogenated ergotamine, the adrenergic blocking actions are less pronounced and vasoconstrictive actions are greater.

Caffeine, also a cranial vasoconstrictor, is added to further enhance the vasoconstrictive effect without the necessity of increasing ergotamine dosage.

Many migraine patients experience excessive nausea and vomiting during attacks, making it impossible for them to retain any oral medication. In such cases, therefore, the only practical means of medication is through the rectal route where medication may reach the cranial vessels directly, evading the splanchnic vasculature and the liver.

INDICATIONS

Cafergot® (ergotamine tartrate and caffeine)

Indicated as therapy to abort or prevent vascular headache, e.g., migraine, migraine variants or so-called "histaminic cephalalgia".

CONTRAINDICATIONS: Peripheral vascular disease, coronary heart disease, hypertension, impaired hepatic or renal function, sepsis and pregnancy.

Hypersensitivity to any of the components.

PRECAUTIONS: Although signs and symptoms of ergotism rarely develop even after long term intermittent use of the orally or rectally administered drugs, care should be exercised to remain within the limits of recommended dosage.

Ergotism is manifested by intense arterial vasoconstriction, producing signs and symptoms of peripheral vascular ischemia. Ergotamine induces vasoconstriction by a direct action on vascular smooth muscle. In chronic intoxication with ergot derivatives, headache, intermittent claudication, muscle pains, numbness, coldness and pallor of the digits may occur. If the condition is allowed to progress untreated, gangrene can result.

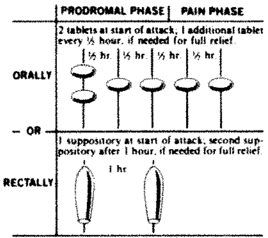
While most cases of ergotism associated with ergotamine treatment result from frank overdosage, some cases have involved apparent hypersensitivity. There are few reports of ergotism among patients taking doses within the recommended limits or for brief periods of time. In rare instances, patients, particularly those who have used the medication indiscriminately over long periods of time, may display withdrawal symptoms consisting of rebound headache upon discontinuation of the drug.

There have been reports of drug abuse and psychological dependence in patients on Cafergot® (ergotamine tartrate and caffeine) therapy. Due to the chronicity of vascular headaches, it is imperative that patients be advised not to exceed recommended dosages with long-term use to avoid ergotism.

ADVERSE REACTIONS: Vasoconstrictive complications, at times of a serious nature, may occur. These include pulselessness, weakness, muscle pains and paresthesias of the extremities and precordial distress and pain. Although these effects occur most commonly with long-term therapy at relatively high doses, they have also been reported with short-term or normal doses. Other adverse effects include transient tachycardia or bradycardia, nausea, vomiting, localized edema and itching.

DOSAGE AND ADMINISTRATION

Procedure: For the best results, dosage should start at the first sign of an attack.



PRODROMAL PHASE
PAIN PHASE
2 tablets at start of attack; 1 additional tablet every ½ hour, if needed for full relief.
½ hr.
½ hr.
½ hr.
½ hr.
ORALLY
— OR —
1 suppository at start of attack; second suppository after 1 hour, if needed for full relief.
1 hr
RECTALLY

Early Administration Gives Maximum Effectiveness

MAXIMUM ADULT DOSAGE

Orally: Total dose for any one attack should not exceed 6 tablets.

Rectally: Two suppositories is the maximum dose for an individual attack.

Total weekly dosage should not exceed 10 tablets or 5 suppositories.

In carefully selected patients, with due consideration of maximum dosage recommendations, administration of the drug at bedtime may be an appropriate short-term preventive measure.

OVERDOSAGE: The toxic effects of an acute overdosage of Cafergot® (ergotamine tartrate and caffeine) are due primarily to the ergotamine component. The amount of caffeine is such that its toxic effects will be overshadowed by those of ergotamine. Symptoms include vomiting, numbness, tingling, pain and cyanosis of the extremities associated with diminished or absent peripheral pulses; hypertension or hypotension; drowsiness, stupor, coma, convulsions and shock. A case has been reported of reversible bilateral papillitis with ring scotomata in a patient who received five times the recommended daily adult dose over a period of 14 days.

Treatment consists of removal of the offending drug by induction of emesis, gastric lavage, and catharsis. Maintenance of adequate pulmonary ventilation, correction of hypotension, and control of convulsions are important considerations. Treatment of peripheral vasospasm should consist of warmth, but not heat, and protection of the ischemic limbs. Vasodilators may be used with benefit but caution must be exercised to avoid aggravating an already existent hypotension.

HOW SUPPLIED

Cafergot® (ergotamine tartrate and caffeine) Tablets

Shell pink colored, sugar coated, imprinted "CAFERGOT" on one side, "S" on other side. Bottles of 250, NDC 0078-0034-28, and cartons of three SigPak® (dispensing unit) packages, each containing 30 tablets in individual blisters, NDC 0078-0034-42.

Cafergot® (ergotamine tartrate and caffeine) Suppositories

Sealed in fuchsia-colored aluminum foil, imprinted "S CAFERGOT® SUPPOSITORY 78-33 SANDOZ". Boxes of 12, NDC 0078-0033-02.

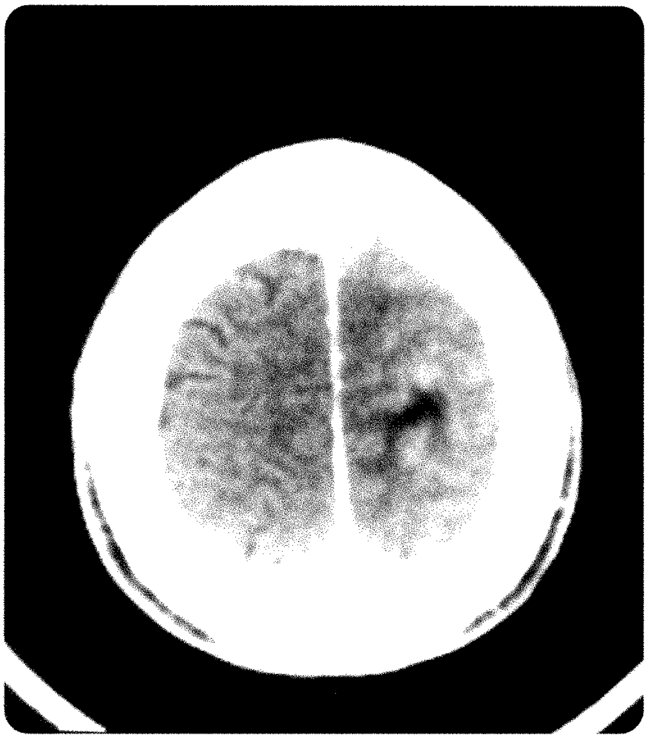
THE DECISION IS YOURS.

COMPARE.

THE CASE: A 40-year-old man presented with a 2-month history of involuntary muscle contractions of the right arm and mild weakness of the left leg.

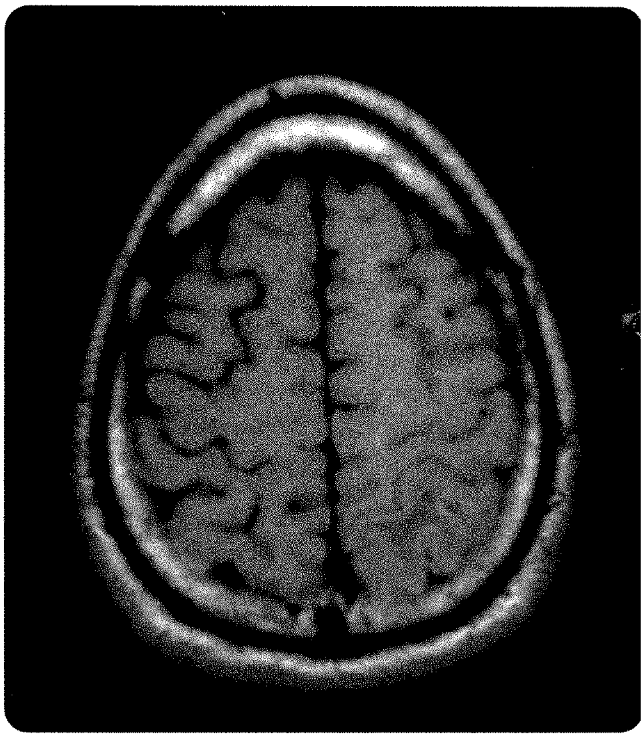
First there was CT.



Contrast CT scan shows an area of low attenuation in the left parietal lobe. A questionable focus of contrast is seen, but this may represent cerebral cortex.

Images courtesy of Michael R. Ross, MD, Stanford University Medical Center, Stanford, California

Then MRI.

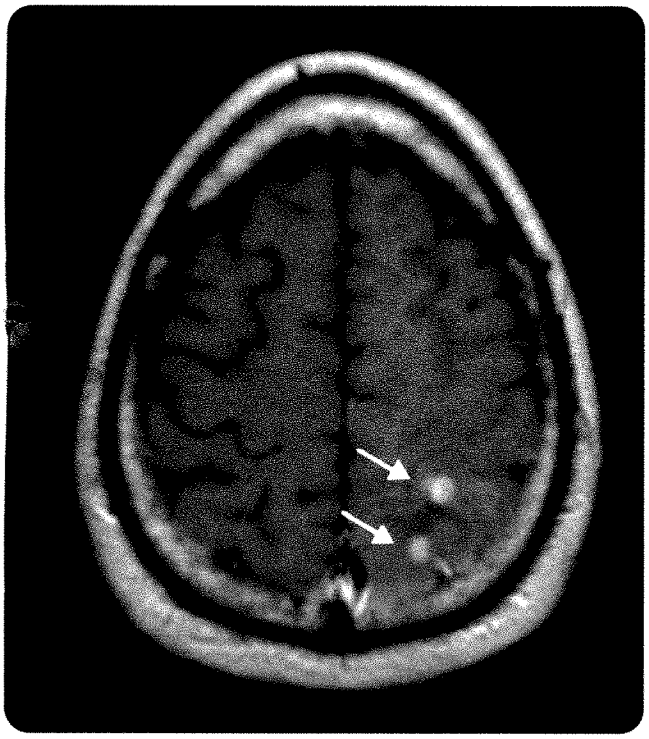


T1-weighted (TR 800/TE 20) unenhanced MR image, obtained with a 1.5-T imager, shows subcortical hypointensity in the left posterior parietal lobe. The surrounding sulci appear to be compressed, but a mass is not clearly appreciated.

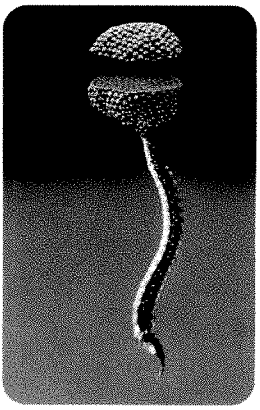
© 1991, Berlex Laboratories, Inc. All rights reserved.

AND CONTRAST.

Now, *Magnevist*®-enhanced MRI lets you see even more.



T1-weighted (TR 800/TE 20) image enhanced with MAGNEVIST® injection reveals two discrete nodules (arrows). This nodular enhancement is highly suggestive of a primary brain tumor, which was confirmed upon biopsy to be an astrocytoma.



Magnevist®

(gadopentetate dimeglumine 469.01 mg/mL)

INJECTION

NOTHING LOCATES LESIONS BETTER

Please see brief summary of prescribing information for MAGNEVIST® injection on last page of this advertisement.

Well tolerated[1] In clinical trials, the most common adverse reactions reported were headache (8.7%) and injection-site coldness/localized coldness (4.8%). The majority of headaches were transient and of mild to moderate severity. In clinical trials, 15% to 30% of patients experienced an asymptomatic transient rise in serum iron; hypotension and anaphylactoid reactions have occurred in less than 1% of the patients. The safety of MAGNEVIST® injection in patients with hemolytic disorders has not been studied.

REFERENCE: 1. Data on file, Berlex Laboratories, Inc.

BRIEF SUMMARY

INDICATIONS AND USAGE

MAGNEVIST® Injection is indicated for use with magnetic resonance imaging (MRI) in adults and children (2 years of age and older) to provide contrast enhancement in those intracranial lesions with abnormal vascularity or those thought to cause an abnormality in the blood-brain barrier. MAGNEVIST® Injection has been shown to facilitate visualization of intracranial lesions including but not limited to tumors.

MAGNEVIST® Injection is also indicated for use with MRI in adults and children (2 years of age and older) to provide contrast enhancement and facilitate visualization of lesions in the spine and associated tissues. There is, however, only limited clinical experience in children for this indication.

CONTRAINDICATIONS

None known.

WARNINGS

The accepted safety considerations and procedures that are required for magnetic resonance imaging are applicable when MAGNEVIST® Injection is used for contrast enhancement. In addition, deoxygenated sickle erythrocytes have been shown in *in vitro* studies to align perpendicular to a magnetic field which may result in vaso-occlusive complications *in vivo*. The enhancement of magnetic moment by gadopentetate dimeglumine may possibly potentiate sickle erythrocyte alignment. MAGNEVIST® Injection in patients with sickle cell anemia and other hemoglobinopathies has not been studied.

Patients with other hemolytic anemias have not been adequately evaluated following administration of MAGNEVIST® Injection to exclude the possibility of increased hemolysis.

Hypotension may occur in some patients after injection of MAGNEVIST® Injection. In clinical trials two cases were reported and in addition, there was one case of a vasovagal reaction and two cases of pallor with dizziness, sweating and nausea in one and substernal pain and flushing in the other. These were reported within 25 to 85 minutes after injection except for the vasovagal reaction which was described as mild by the patient and occurred after 6-1/2 hours. In a study in normal volunteers one subject experienced syncope after arising from a sitting position two hours after administration of the drug. Although the relationship of gadopentetate dimeglumine to these events is uncertain, patients should be observed for several hours after drug administration.

Magnevist®
(gadopentetate dimeglumine 469.01 mg/mL)
INJECTION

PRECAUTIONS - General

Diagnostic procedures that involve the use of contrast agents should be carried out under direction of a physician with the prerequisite training and a thorough knowledge of the procedure to be performed.

In a patient with a history of grand mal seizures, MAGNEVIST® Injection was reported to induce such a seizure.

Since gadopentetate dimeglumine is cleared from the body by glomerular filtration, caution should be exercised in patients with severely impaired renal function.

The possibility of a reaction, including serious, life-threatening, fatal, anaphylactoid or cardiovascular reactions or other idiosyncratic reactions should always be considered (see ADVERSE REACTIONS) especially in those patients with a known clinical hypersensitivity.

Animal studies suggest that gadopentetate dimeglumine may alter red cell membrane morphology resulting in a slight degree of extravascular (splenic) hemolysis. In clinical trials 15-30% of the patients experienced an asymptomatic transient rise in serum iron. Serum bilirubin levels were slightly elevated in approximately 3.4% of patients. Levels generally returned to baseline within 24 to 48 hours. Hematocrit and red blood cell count were unaffected and liver enzymes were not elevated in these patients. While the effects of gadopentetate dimeglumine on serum iron and bilirubin have not been associated with clinical manifestations, the effect of the drug in patients with hepatic disease is not known and caution is therefore advised.

When MAGNEVIST® Injection is to be injected using plastic disposable syringes, the contrast medium should be drawn into the syringe and used immediately.

If nondisposable equipment is used, scrupulous care should be taken to prevent residual contamination with traces of cleansing agents.

Repeat Procedures: If in the clinical judgment of the physician sequential or repeat examinations are required, a suitable interval of time between administrations should be observed to allow for normal clearance of the drug from the body.

Information for Patients:

Patients receiving MAGNEVIST® Injection should be instructed to:

1. Inform your physician if you are pregnant or breast feeding.
2. Inform your physician if you have anemia or any diseases that affect red blood cells.

LABORATORY TEST FINDINGS

Transitory changes in serum iron and bilirubin levels have been reported in patients with normal and abnormal liver function (See PRECAUTIONS - General).

CARCINOGENESIS, MUTAGENESIS, AND IMPAIRMENT OF FERTILITY

No animal studies have been performed to evaluate the carcinogenic potential of gadopentetate dimeglumine.

Gadopentetate dimeglumine did not evoke any evidence of mutagenic potential in the Ames test (histidine-dependent *Salmonella typhimurium*) nor in a reverse mutation assay using tryptophan-dependent *Escherichia coli*. Gadopentetate dimeglumine did not induce a positive response in the (C3H 10T1/2) mouse embryo fibroblast cellular transformation assay, nor did it induce unscheduled DNA repair synthesis in primary cultures of rat hepatocytes at concentrations up to 5000 μg/mL. However, the drug did show some evidence of mutagenic potential *in vivo* in the mouse dominant lethal assay at doses of 6 mmol/kg, but did not show any such potential in the mouse and dog micronucleus tests at intravenous doses of 9 mmol/kg and 2.5 mmol/kg, respectively.

The results of a reproductive study in rats showed that gadopentetate dimeglumine when administered in daily doses of 0.1-2.5 mmol/kg, did not cause a significant change in the pregnancy rate in comparison to a control group. However, suppression of body weight gain and food consumption and a decrease in the mean weights of testis and epididymis occurred in male rats at the 2.5 mmol/kg dose. In female rats a decrease in the number of corpora lutea at the 0.1 mmol/kg dose and the suppression of body weight gain and food consumption at the 2.5 mmol/kg dose were observed.

In a separate experiment, 16 daily intravenous injections were administered to male rats. At a dose of 5 mmol/kg of gadopentetate dimeglumine, spermatogenic cell atrophy was observed. This atrophy was not reversed within a 16-day observation period following the discontinuation of the drug. This effect was not observed at a dose of 2.5 mmol/kg.

PREGNANCY CATEGORY C.

Gadopentetate dimeglumine has been shown to retard development slightly in rats when given in doses 2.5 times the human dose, and in rabbits when given in doses of 7.5 and 12.5 times the human dose. The drug did not exhibit this effect in rabbits when given in doses 2.5 times the human dose. No congenital anomalies were noted in either species.

There are no adequate and well-controlled studies in pregnant women. MAGNEVIST® Injection should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS

C^{14} labelled gadopentetate dimeglumine was administered intravenously to lactating rats at a dose of 0.5 mmol/kg. Less than 0.2% of the total dose was transferred to the neonate via the milk during the 24-hour evaluation period. It is not known to what extent MAGNEVIST® Injection is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when the drug is administered to a nursing mother and consideration should be given to temporarily discontinuing nursing.

PEDIATRIC USE

Safety and efficacy in children under the age of 2 years have not been established. (See Indications and Usage and Dosage and Administration sections).

ADVERSE REACTIONS

The most commonly noted adverse experience is headache with an incidence of 8.7%. The majority of headaches are transient and of mild to moderate severity. In 42.3% of the cases it was felt that the headaches were not related to MAGNEVIST® Injection. Injection site coldness/localized coldness is the second most common adverse experience at 4.8%. Nausea occurs in 3.2% of the patients.

Localized pain, vomiting, paresthesia, dizziness and localized warmth occur in less than 2% of the patients.

The following additional adverse events occur in less than 1% of the patients:

Body as a Whole: Injection site symptoms, namely, pain, warmth, burning; localized burning sensation, substernal chest pain, fever, weakness, generalized coldness, localized edema, tiredness, chest tightness, regional lymphangitis, anaphylactoid reactions (characterized by cardiovascular, respiratory and cutaneous symptoms).

Cardiovascular: Hypotension, vasodilation, pallor, non-specific ECG changes, angina pectoris, phlebitis.

Digestive: Gastrointestinal distress, stomach pain, teeth pain, increased salivation.

Nervous System: Agitation, thirst, convulsions (including grand mal).

Respiratory System: Throat irritation, rhinorrhea, sneezing, dyspnea, wheezing, laryngismus, cough.

Skin: Rash, sweating, pruritus, urticaria (hives).

Special Senses: Tinnitus, conjunctivitis, visual field defect, taste abnormality, dry mouth, lacrimation disorder (tearing), eye irritation.

Laboratory: Transient elevation of serum transaminases.

The following other adverse events were reported. A causal relationship has neither been established nor refuted.

Body as a Whole: Back pain, pain, generalized warmth.

Cardiovascular: Hypertension, tachycardia, migraine, syncope, death related to myocardial infarction or other undetermined causes.

Digestive: Constipation, diarrhea.

Nervous System: Anxiety, anorexia, nystagmus, drowsiness, diplopia, stupor.

Skin: Facial edema, erythema multiforme, epidermal necrolysis.

Special Senses: Eye pain, ear pain.

Data from foreign studies did not reveal any additional adverse experiences.

OVERDOSAGE

The LD_{50} of intravenously administered gadopentetate dimeglumine injection in mice is 5-12.5 mmol/kg and in rats it is 10-15 mmol/kg. The LD_{50} of intravenously administered MAGNEVIST® Injection in dogs is greater than 6 mmol/kg.

Clinical consequences of overdose with MAGNEVIST® Injection have not been reported.

DOSAGE AND ADMINISTRATION

The recommended dosage of MAGNEVIST® Injection is 0.2 mL/kg (0.1 mmol/kg), administered intravenously, at a rate not to exceed 10 mL per minute. More rapid injection rates may be associated with nausea. The maximum total dose is 20 mL. Any unused portion must be discarded.

DOSAGE CHART

Body Weight (kg)	Dose in mL	Approx Duration of Injection in Seconds
10	2.0	20
20	4.0	30
30	6.0	40
40	8.0	50
50	10.0	60
60	12.0	70
70	14.0	80
80	16.0	95
90	18.0	110
100	20.0	120

To ensure complete injection of the contrast medium, the injection should be followed by a 5-mL normal saline flush. The imaging procedure should be completed within 1 hour of injection of MAGNEVIST® Injection.

Parenteral products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

For full prescribing information, see package insert.

Caution: Federal Law Prohibits Dispensing Without Prescription.

	14-18	The Second Dartmouth International Conference on the Corpus Callosum and Epilepsy, Dartmouth-Hitchcock Medical Center, Hanover, NH. Contact Alexander G. Reeves, MD, Section of Neurology, Dartmouth-Hitchcock Medical Center, Hanover, NH 03756.

Damasio Selected to Receive American Medical Association Award.—An international leader in the field of cognitive neuroscience at the University of Iowa College of Medicine, Iowa City, was selected to receive the American Medical Association's Dr William Beaumont Award for 1990.

Dr Antonio R. Damasio, Maurice Van Allen professor and head of the neurology department, was chosen to receive the award presented annually to a physician, under age 50 years, who has made an outstanding contribution to medical research. This is one of five major honors awarded by the association at its annual convention, June 24 through 28, in Chicago.

For the past 15 years, "Dr Damasio has made landmark contributions to the understanding of the areas of the brain responsible for mental activities; this award recognizes him as a leader in the field of cognitive neuroscience," says Dr John W. Eckstein, dean of the University of Iowa College of Medicine.

Damasio and his colleagues have identified areas of the human brain that are critical for color perception, reading, and face recognition; shown that the brain assigns different types of knowledge, such as man-made objects, natural kinds, language codes, and social conduct, to entirely different neural systems; and discovered that Alzheimer's disease destroys specific nerve cells in a particular area of the brain, and that the cell loss is accompanied by degeneration of a brain neurotransmitter pathway. These specific changes are a key mechanism behind the memory loss, the hallmark of Alzheimer's disease.

The Dr William Beaumont Award consists of a cash stipend and a plaque that was presented to Dr Damasio during an award ceremony at the association's annual convention.

When the world turns upside down...

Transderm Scōp is the better choice for motion sickness prevention

- more effective than 25 mg meclizine and Dramamine®[1,2]
- better compliance because transdermal delivery is more convenient

Transderm Scōp®
scopolamine
programmed delivery
0.5 mg over 72 hrs

Transderm Scōp should not be used in children. Use with special care in the elderly and in patients taking drugs (including alcohol) capable of causing CNS effects. Dryness of the mouth occurs in about two thirds of people. Please see Prescribing Information on next page before prescribing.

CIBA

Transderm Scōp®

scopolamine
(formerly Transderm-V)

Transdermal Therapeutic System

Programmed delivery *in vivo* of 0.5 mg of scopolamine over 3 days

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE

Transderm Scōp is indicated for prevention of nausea and vomiting associated with motion sickness in adults. The disc should be applied only to skin in the postauricular area.

Clinical Results: Transderm Scōp provides antiemetic protection within several hours following application of the disc behind the ear. In 195 adult subjects of different racial origins who participated in clinical efficacy studies at sea or in a controlled motion environment, there was a 75% reduction in the incidence of motion-induced nausea and vomiting. Transderm Scōp provided significantly greater protection than that obtained with oral dimenhydrinate.

CONTRAINDICATIONS

Transderm Scōp should not be used in patients with known hypersensitivity to scopolamine or any of the components of the adhesive matrix making up the therapeutic system, or in patients with glaucoma.

WARNINGS

Transderm Scōp should not be used in children and should be used with special caution in the elderly. See **PRECAUTIONS.**

Since drowsiness, disorientation, and confusion may occur with the use of scopolamine, patients should be warned of the possibility and cautioned against engaging in activities that require mental alertness, such as driving a motor vehicle or operating dangerous machinery.

Potentially alarming idiosyncratic reactions may occur with ordinary therapeutic doses of scopolamine.

PRECAUTIONS

General

Scopolamine should be used with caution in patients with pyloric obstruction, or urinary bladder neck obstruction. Caution should be exercised when administering an antiemetic or antimuscarinic drug to patients suspected of having intestinal obstruction.

Transderm Scōp should be used with special caution in the elderly or in individuals with impaired metabolic, liver, or kidney functions, because of the increased likelihood of CNS effects.

Information for Patients

Since scopolamine can cause temporary dilation of the pupils and blurred vision if it comes in contact with the eyes, patients should be strongly advised to wash their hands thoroughly with soap and water immediately after handling the disc.

Patients should be advised to remove the disc immediately and contact a physician in the unlikely event that they experience symptoms of acute narrow-angle glaucoma (pain in and reddening of the eyes accompanied by dilated pupils).

Patients should be warned against driving a motor vehicle or operating dangerous machinery. A patient brochure is available.

Drug Interactions

Scopolamine should be used with care in patients taking drugs, including alcohol, capable of causing CNS effects. Special attention should be given to drugs having anticholinergic properties, e.g., belladonna alkaloids, antihistamines (including meclizine), and antidepressants.

Carcinogenesis, Mutagenesis, Impairment of Fertility

No long-term studies in animals have been performed to evaluate carcinogenic potential. Fertility studies were performed in female rats and revealed no evidence of impaired fertility or harm to the fetus due to scopolamine hydrobromide administered by daily subcutaneous injection. In the highest-dose group (plasma level approximately 500 times the level achieved in humans using a transdermal system), reduced maternal body weights were observed.

Pregnancy Category C

Teratogenic studies were performed in pregnant rats and rabbits with scopolamine hydrobromide administered by daily intravenous injection. No adverse effects were recorded in the rats. In the rabbits, the highest dose (plasma level approximately 100 times the level achieved in humans using a transdermal system) of drug administered had a marginal embryotoxic effect. Transderm Scōp should be used during pregnancy only if the anticipated benefit justifies the potential risk to the fetus.

Nursing Mothers

It is not known whether scopolamine is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Transderm Scōp is administered to a nursing woman.

Pediatric Use

Children are particularly susceptible to the side effects of belladonna alkaloids. Transderm Scōp should not be used in children because it is not known whether this system will release an amount of scopolamine that could produce serious adverse effects in children.

ADVERSE REACTIONS

The most frequent adverse reaction to Transderm Scōp is dryness of the mouth. This occurs in about two thirds of the people. A less frequent adverse reaction is drowsiness, which occurs in less than one sixth of the people. Transient impairment of eye accommodation, including blurred vision and dilation of the pupils, is also observed.

The following adverse reactions have also been reported on infrequent occasions during the use of Transderm Scōp: disorientation; memory disturbances; dizziness; restlessness; hallucinations; confusion; difficulty urinating; rashes and erythema; acute narrow-angle glaucoma; and dry, itchy, or red eyes.

Drug Withdrawal: Symptoms including dizziness, nausea, vomiting, headache and disturbances of equilibrium have been reported in a few patients following discontinuation of the use of the Transderm Scōp system. These symptoms have occurred most often in patients who have used the systems for more than three days.

OVERDOSAGE

Overdosage with scopolamine may cause disorientation, memory disturbances, dizziness, restlessness, hallucinations, or confusion. Should these symptoms occur, the Transderm Scōp disc should be immediately removed. Appropriate parasympathomimetic therapy should be initiated if these symptoms are severe.

DOSAGE AND ADMINISTRATION

Initiation of Therapy: One Transderm Scōp disc (programmed to deliver 0.5 mg of scopolamine over 3 days) should be applied to the hairless area behind one ear at least 4 hours before the antiemetic effect is required. Only one disc should be worn at any time.

Handling: *After the disc is applied on dry skin behind the ear, the hands should be washed thoroughly with soap and water and dried. Upon removal of the disc, it should be discarded, and the hands and application site washed thoroughly with soap and water and dried, to prevent any traces of scopolamine from coming into direct contact with the eyes. (A patient brochure is available.)*

Continuation of Therapy: Should the disc become displaced, it should be discarded, and a fresh one placed on the hairless area behind the other ear. If therapy is required for longer than 3 days, the first disc should be discarded, and a fresh one placed on the hairless area behind the other ear.

The system should be stored between 59°-86°F (15°-30°C).

CAUTION

Federal law prohibits dispensing without prescription.

1991
International Conference
on Physician Health

June 6-8, 1991
Toronto, Ontario, Canada

Sponsored by
American Medical Association
Canadian Medical Association
Federation of Medical Licensing
Authorities of Canada

This year's conference, *Caring for the Caregiver*, will address a range of issues relative to physician health, including aging, physical disabilities, psychiatric disorders, and substance abuse. Through the presentation of scientific data and the provision of training workshops, this conference will offer an overview of the current status of the field as well as educational opportunities for the conference participants.

Please join the AMA, CMA, and Federation for this exciting and innovative conference, which:

- Gives participants an opportunity to hear of the latest developments in this important field
- Provides opportunity to learn skills necessary for conducting research in various areas of physician health
- Examines the differing treatment programs and their relative values
- Offers these important features–
    - State-of-the-art research presentations
    - Invited speakers
    - Selected workshops
    - Pre-conference institutes
    - Extensive networking opportunities
    - Exhibits

For more information regarding registration call **toll-free 1-800-621-8335.** For event sponsorship, or invitation to exhibit call Patrick W. McGuffin, PhD, at 1-312-464-4064.

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, Robert J. Joynt, MD, PhD, University of Rochester School of Medicine and Dentistry, 601 Elmwood Ave, Rochester, NY 14642. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

Cover Letter.—Designate one author as correspondent and provide a complete address and telephone number.

In the cover letter include (1) statement on authorship responsibility, (2) statement on financial disclosure, and (3) one of the two following statements on copyright *or* federal employment. Each of these three statements must be signed by *all* authors.

1. Authorship Responsibility.—"I certify that I have participated sufficiently in the conception and design of this work and the analysis of the data (when applicable), as well as the writing of this manuscript, to take public responsibility for it. I believe the manuscript represents valid work. I have reviewed the final version of the manuscript and approve it for publication. Neither this manuscript nor one with substantially similar content under my authorship has been published or is being considered for publication elsewhere, except as described in an attachment. Furthermore, I attest that I shall produce the data upon which the manuscript is based for examination by the editors or their assignees if requested."

2. Financial Disclosure.—"I certify that affiliations (if any) with or involvement in any organization or entity with a direct financial interest in the subject matter or materials discussed in the manuscript (eg, employment, consultancies, stock ownership, honoraria, expert testimony) are disclosed below."

Research or project support should be listed in an acknowledgement.

3a. Copyright Transfer.—"In consideration of the action of the American Medical Association (AMA) in reviewing and editing this submission, the author(s) undersigned hereby transfer(s) assign(s), or otherwise convey(s) all copyright ownership to the AMA in the event that such work is published by the AMA."

3b. Federal Employment.—"I was an employee of the US federal government when this work was investigated and prepared for publication; therefore, it is not protected by the Copyright Act and there is no copyright of which the ownership can be transferred."

We regret that transmittal letters not containing the preceding language signed by all authors of the submission will necessitate delay in review of the manuscript.

Editing.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit three high-quality copies of the entire manuscript. The copies will not be returned. The authors should keep the original manuscript for submission if accepted. The original manuscript (including references, legends, and tables) must be typed double-spaced on 21.6 × 27.9-cm 8½ × 11-in), heavy-duty white bond paper. Ample margins of at least 2.5 cm (1 in) should be provided. **If a word processor is used, do not justify right-hand margins.**

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, and the address to which requests for reprints should be sent.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author(s) (list all authors and/or editors up to six; if more than six, list the first three and "et al"), (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) year, (5) volume number, and (6) inclusive page numbers, in that order. References to books should include (1) author(s) (list all authors and/or editors up to six; if more than six, list the first three and "et al"), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. **The author is responsible for the accuracy and completeness of the references and for their correct text citation.**

SI Units.—Use Système International (SI) measurements throughout the manuscript. (See June 1986 issue of the ARCHIVES.)

Illustrations.—The illustrations originally submitted will not be returned. High-quality copies may be used. Original illustrations should be kept by the author for submission if the manuscript is accepted. Use only those illustrations that clarify and augment the text. If accepted, submit illustrations in triplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.7 × 7.3 cm (5 × 7 in).

Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the ARCHIVES' contribution, the author's share is $400 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

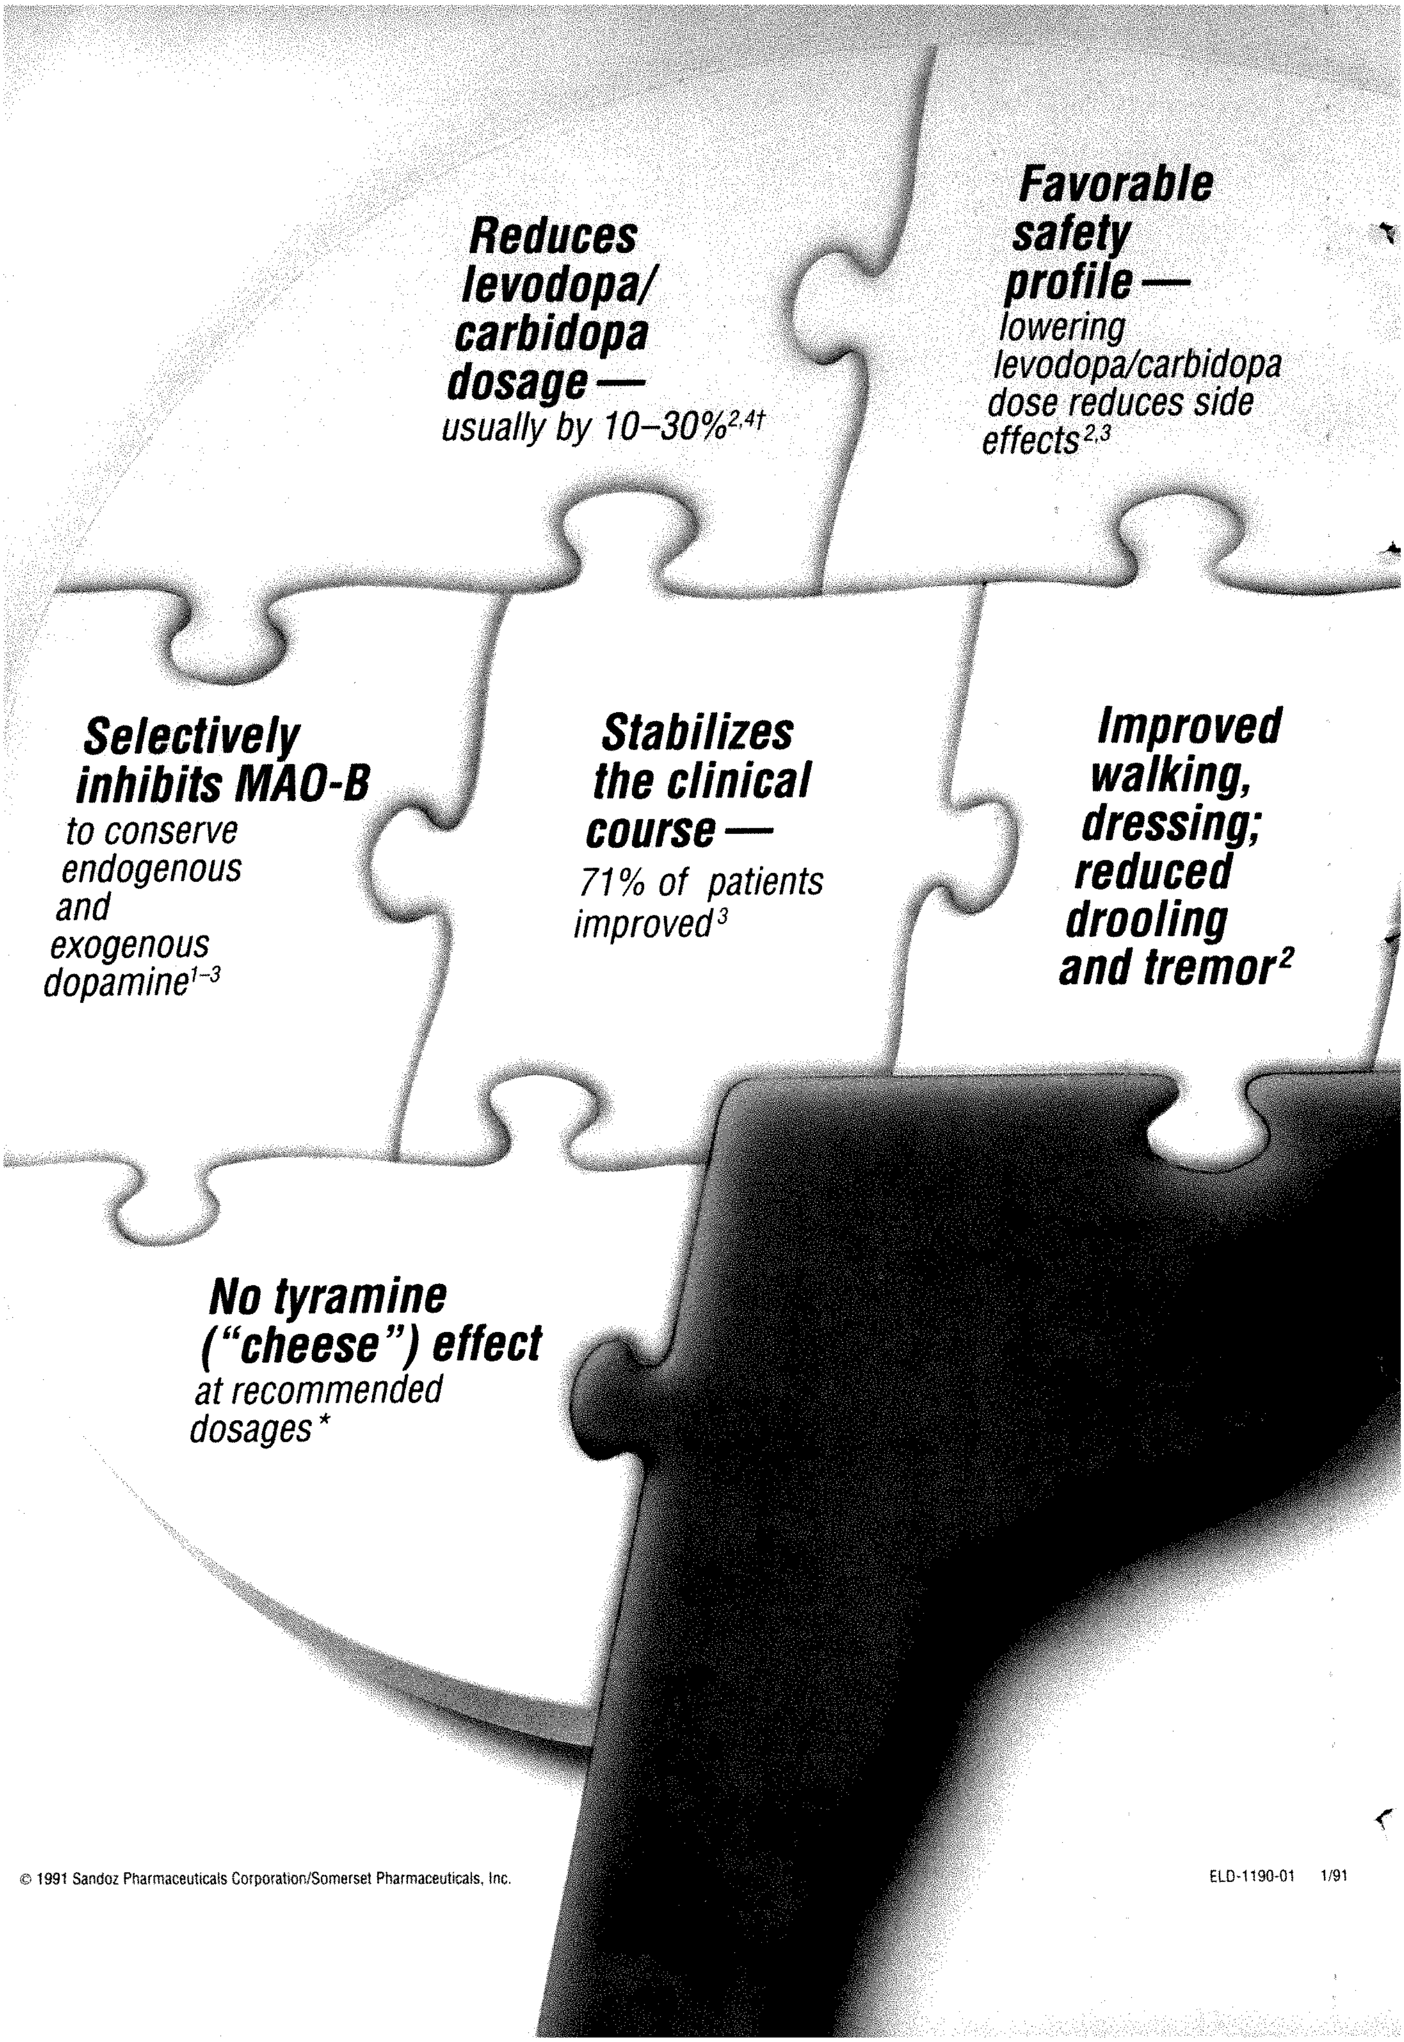
Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the ARCHIVES after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9-cm (8½ × 11-in) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.



Reduces levodopa/ carbidopa dosage — *usually by 10–30%[2,4†]*

Favorable safety profile — *lowering levodopa/carbidopa dose reduces side effects[2,3]*

Selectively inhibits MAO-B *to conserve endogenous and exogenous dopamine[1–3]*

Stabilizes the clinical course — *71% of patients improved[3]*

Improved walking, dressing; reduced drooling and tremor[2]

No tyramine ("cheese") effect *at recommended dosages**

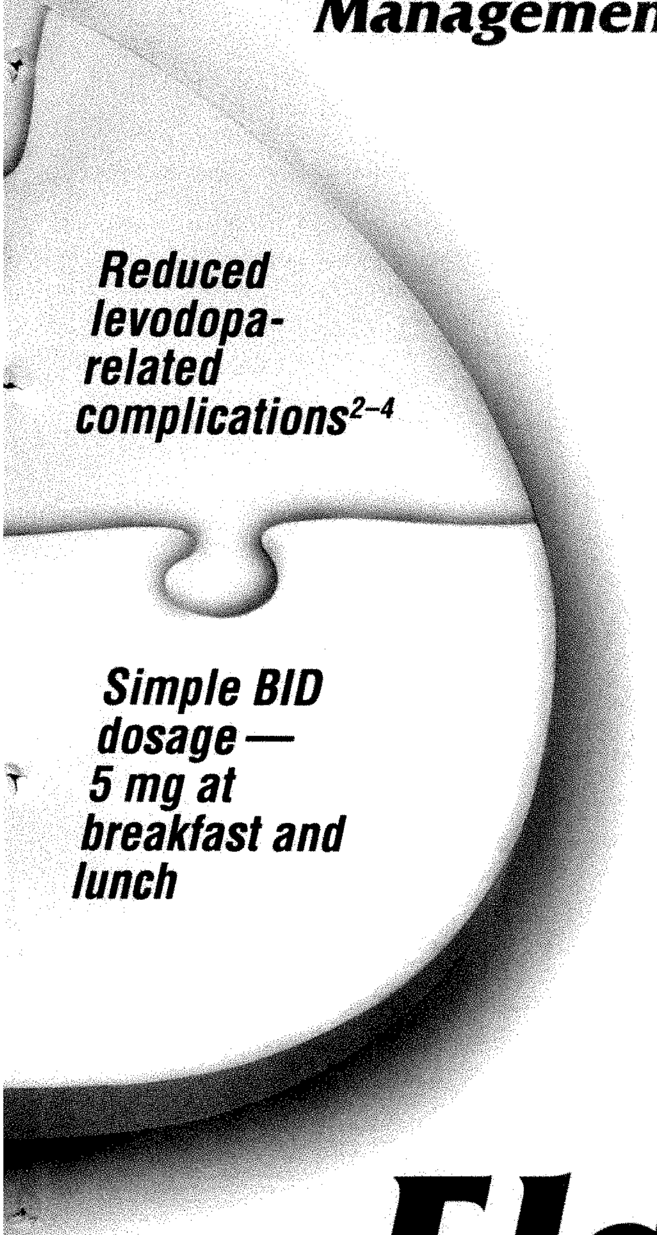
ELD-1190-01 1/91

Management of Parkinson's disease...
still a puzzle



Reduced levodopa-related complications[2–4]
Simple BID dosage — 5 mg at breakfast and lunch

Benefits that provide a fitting solution

Eldepryl®

(SELEGILINE HYDROCHLORIDE)

Fits your therapeutic strategy

*Higher doses have not been shown to increase benefit and have increased the risk of side effects. Please see Dosage and Administration section of prescribing information.

†Further reduction of levodopa/carbidopa may be possible during continued selegiline therapy.

See next page for brief summary of prescribing information.

Eldepryl®

(SELEGILINE HYDROCHLORIDE)

BRIEF SUMMARY

CLINICAL PHARMACOLOGY:

The mechanisms accounting for selegiline's beneficial adjunctive action in the treatment of Parkinson's disease are not fully understood. Inhibition of monoamine oxidase, type B, activity is generally considered to be of primary importance; in addition, there is evidence that selegiline may act through other mechanisms to increase dopaminergic activity.

INDICATIONS AND USAGE:

ELDEPRYL® (SELEGILINE HYDROCHLORIDE) is indicated as an adjunct in the management of Parkinsonian patients being treated with levodopa/carbidopa who exhibit deterioration in the quality of their response to this therapy. There is no evidence from controlled studies that selegiline has any beneficial effect in the absence of concurrent levodopa therapy.

Evidence supporting this claim was obtained in randomized controlled clinical investigations that compared the effects of added selegiline or placebo in patients receiving levodopa/carbidopa. Selegiline was significantly superior to placebo on all three principal outcome measures employed: change from baseline in daily levodopa/carbidopa dose, the amount of 'off' time, and patient self-rating of treatment success. Beneficial effects were also observed on other measures of treatment success (e.g., measures of reduced end of dose akinesia, decreased tremor and sialorrhea, improved speech and dressing ability and improved overall disability as assessed by walking and comparison to previous state).

CONTRAINDICATIONS:

ELDEPRYL® (SELEGILINE HYDROCHLORIDE) is contraindicated in patients with a known hypersensitivity to this drug.

WARNINGS:

Selegiline should not be used at daily doses exceeding those recommended (10 mg/day) because of the risks associated with non-selective inhibition of MAO. (See CLINICAL PHARMACOLOGY.)

The selectivity of selegiline for MAO B may not be absolute even at the recommenced daily dose of 10 mg a day and selectivity is further diminished with increasing daily doses. The precise dose at which selegiline becomes a non-selective inhibitor of all MAO is unknown, but may be in the range of 30 to 40 mg a day.

Because of reports of fatal interactions, MAOIs are ordinarily contraindicated for use with meperidine (DEMEROL & other tradenames). This warning is often extended to other opioids. Because the mechanism of interaction between MAOIs and meperidine is unknown, it seems prudent, in general, to avoid this combination.

Definitive clinical data on the concomitant use of ELDEPRYL® (SELEGILINE HYDROCHLORIDE) and fluoxetine hydrochloride (PROZAC) is not available. Death has been reported to occur following the initiation of therapy with nonselective MAOI's (NARDIL, PARNATE) shortly after discontinuation of fluoxetine. To date, this reaction has not been reported with ELDEPRYL® (SELEGILINE HYDROCHLORIDE), however, since the mechanism of this reaction is not fully understood it seems prudent, in general, to avoid this combination. Because of the long half-lives of fluoxetine and its active metabolite, at least five weeks (approximately 5 half-lives) should elapse beweeen discontinuation of fluoxetine and initiation of MAOI therapy. Based on experience with the combined use of MAOI's and tricyclic antidepressants, at least 14 days should elapse between discontinuation of an MAOI and initiation of treatment with fluoxetine.

PRECAUTIONS:

General: Some patients given selegiline may experience an exacerbation of levodopa associated side effects, presumably due to the increased amounts of dopamine reacting with super-sensitive post-synaptic receptors. These effects may often be mitigated by reducing the dose of levodopa/carbidopa by approximately 10 to 30%.

The decision to prescribe selegiline should take into consideration that the MAO system of enzymes is complex and incompletely understood and there is only a limited amount of carefully documented clinical experience with selegiline. Consequently, the full spectrum of possible responses to selegiline may not have been observed in pre-marketing evaluation of the drug. It is advisable, therefore, to observe patients closely for atypical responses.

Information for Patients: Patients should be advised of the possible need to reduce levodopa dosage after the initiation of ELDEPRYL® (SELEGILINE HYDROCHLORIDE) therapy.

Patients (or their families if the patient is incompetent) should be advised not to exceed the daily recommended dose of 10 mg. The risk of using higher daily doses of selegiline should be explained, and a brief description of the 'cheese reaction' provided. While hypertensive reactions with selegiline have not been reported, documented experience is limited. Consequently, it may be useful to inform patients (or their families) about the signs and symptoms associated with MAOI induced hypertensive reactions. In particular, patients should be urged to report, immediately, any severe headache or other atypical or unusual symptoms not previously experienced.

Laboratory Tests: No specific laboratory tests are deemed essential for the management of patients on ELDEPRYL® (SELEGILINE HYDROCHLORIDE). Periodic routine evaluation of all patients, however, is appropriate.

Drug Interactions: No interactions attributed to the combined use of selegiline and other drugs have been reported. However, because the database of documented clinical experience is limited, the level of reassurance provided by this lack of adverse reporting is uncertain. (See WARNINGS and PRECAUTIONS.)

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Studies have not been performed to date to evaluate the carcinogenic potential of selegiline hydrochloride.

Pregnancy: *Pregnancy Category C.* Insufficient animal reproduction studies have been done with selegiline to conclude that selegiline poses no teratogenic risk. However, one rat study carried out at doses as much as 180 fold the recommended human dose revealed no evidence of a teratogenic effect. It is not known whether selegiline can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Selegiline should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether selegiline hydrochloride is excreted in human milk. Because many drugs are excreted in human milk, consideration should be given to discontinuing the use of all but absolutely essential drug treatments in nursing women.

Pediatric Use: The effects of selegiline hydrochloride in children have not been evaluated.

ADVERSE REACTIONS:

Introduction: The number of patients who received selegiline in prospectively monitored pre-marketing studies is limited. While other sources of information about the use of selegiline are available (e.g., literature reports, foreign post-marketing reports, etc.) they do not provide the kind of information necessary to estimate the incidence of adverse events. Thus, overall incidence figures for adverse reactions associated with the use of selegiline cannot be provided. Many of the adverse reactions seen have been also reported as symptoms of dopamine excess.

Moreover, the importance and severity of various reactions reported often cannot be ascertained. One index of relative importance, however, is whether or not a reaction caused treatment discontinuation. In prospective pre-marketing studies, the following events led, in decreasing order of frequency, to discontinuation of treatment with selegiline: nausea, hallucinations, confusion, depression, loss of balance, insomnia, orthostatic hypotension, increased akinetic involuntary movements, agitation, arrhythmia, bradykinesia, chorea, delusions, hypertension, new or increased angina pectoris and syncope. Events reported only once as a cause of discontinuation are ankle edema, anxiety, burning lips/mouth, constipation, drowsiness/lethargy, dystonia, excess perspiration, increased freezing, gastrointestinal bleeding, hair loss, increased tremor, nervousness, weakness and weight loss.

Experience with ELDEPRYL® (SELEGILINE HYDROCHLORIDE) obtained in parallel, placebo controlled, randomized studies provides only a limited basis for estimates of adverse reaction rates. The following reactions that occurred with greater frequency among the 49 patients assigned to selegiline as compared to the 50 patients assigned to placebo in the only parallel, placebo controlled trial performed in patients with Parkinson's disease are shown in the following Table. None of these adverse reactions led to a discontinuation of treatment.

In all prospectively monitored clinical investigations, enrolling approximately 920 patients, the following adverse events, classified by body system, were reported.

CENTRAL NERVOUS SYSTEM:

Motor/Coordination/Extrapyramidal: increased tremor, chorea, loss of balance, restlessness, blephorospasm, increased bradykinesia, facial grimace, falling down, heavy leg, muscle twitch*, myoclonic jerks*, stiff neck, tardive dyskinesia, dystonic symptoms, dyskinesia, involuntary movements, freezing, festination, increased apraxia, muscle cramps.

Mental Status/Behavioral/Psychiatric: hallucinations, dizziness, confusion, anxiety, depression, drowsiness, behavior/mood change, dreams/nightmares, tiredness, delusions, disorientation, lightheadedness, impaired memory*, increased energy*, transient high*, hollow feeling, lethargy/malaise, apathy, overstimulation, vertigo, personality change, sleep disturbance, restlessness, weakness, transient irritability.

Pain/Altered Sensation: headache, back pain, leg pain, tinnitus, migraine, supraorbital pain, throat burning, generalized ache, chills, numbness of toes/fingers, taste disturbance.

AUTONOMIC NERVOUS SYSTEM: Dry mouth, blurred vision, sexual dysfunction.

CARDIOVASCULAR: Orthostatic hypotension, hypertension, arrhythmia, palpitations, new or increased angina pectoris, hypotension, tachycardia, peripheral edema, sinus bradycardia, syncope.

GASTROINTESTINAL: Nausea/vomiting, constipation, weight loss, anorexia, poor appetite, dysphagia, diarrhea, heartburn, rectal bleeding, bruxism*, gastrointestinal bleeding (exacerbation of preexisting ulcer disease).

GENITOURINARY/GYNECOLOGIC/ENDOCRINE: Slow urination, transient anorgasmia*, nocturia, prostatic hypertrophy, urinary hesitancy, urinary retention, decreased penile sensation*, urinary frequency.

SKIN AND APPENDAGES: Increased sweating, diaphoresis, facial hair, hair loss, hemotoma, rash, photosensitivity.

MISCELLANEOUS: Asthma, diplopia, shortness of breath, speech affected.

POSTMARKETING REPORTS: The following experiences were described in spontaneous postmarketing reports. These reports do not provide sufficient information to establish a clear causal relationship with the use of ELDEPRYL® (SELEGILINE HYDROCHLORIDE).

CNS: Seizure in dialyzed chronic renal failure patient on concomitant medications.

*indicates events reported only at doses greater than 10 mg/day.

Incidence of Treatment-Emergent Adverse Experiences in the Placebo-Controlled Clinical Trial

Adverse Event	Number of Patients Reporting Events	
	selegiline hydrochloride N = 49	placebo N = 50
Nausea	10	3
Dizziness/Lightheaded/Fainting	7	1
Abdominal Pain	4	2
Confusion	3	0
Hallucinations	3	1
Dry mouth	3	1
Vivid Dreams	2	0
Dyskinesias	2	5
Headache	2	1
The following events were reported once in either or both groups:		
Ache, generalized	1	0
Anxiety/Tension	1	1
Anemia	0	1
Diarrhea	1	0
Hair Loss	0	1
Insomnia	1	1
Lethargy	1	0
Leg pain	1	0
Low back pain	1	0
Malaise	0	1
Palpitations	1	0
Urinary Retention	1	0
Weight Loss	1	0

OVERDOSAGE:

Selegiline: No specific information is available about clinically significant overdoses with ELDEPRYL® (SELEGILINE HYDROCHLORIDE). However, experience gained during selegiline's development reveals that some individuals exposed to doses of 600 mg d,l selegiline suffered severe hypotension and psychomotor agitation.

Since the selective inhibition of MAO B by selegiline hydrochloride is achieved only at doses in the range recommended for the treatment of Parkinson's disease (e.g., 10 mg/day), overdoses are likely to cause significant inhibition of both MAO A and MAO B. Consequently, the signs and symptoms of overdose may resemble those observed with marketed non-selective MAO inhibitors (e.g., tranylcypromine (PARNATE), isocarboxazide (MARPLAN), and phenelzine (NARDIL)).

Overdose with Non-Selective MAO Inhibition: NOTE: This section is provided for reference; it does not describe events that have actually been observed with selegiline in overdose.

Characteristically, signs and symptoms of non-selective MAOI overdose may not appear immediately. Delays of up to 12 hours between ingestion of drug and the appearance of signs may occur. Importantly, the peak intensity of the syndrome may not be reached for upwards of a day following the overdose. Death has been reported following overdosage. Therefore, immediate hospitalization, with continuous patient observation and monitoring for a period of at least two days following the ingestion of such drugs in overdose is strongly recommended.

The clinical picture of MAOI overdose varies considerably; its severity may be a function of the amount of drug consumed. The central nervous and cardiovascular systems are prominently involved.

Signs and symptoms of overdosage may include, alone or in combination, any of the following: drowsiness, dizziness, faintness, irritability, hyperactivity, agitation, severe headache, hallucinations, trismus, opisthotonus, convulsions, and coma; rapid and irregular pulse, hypertension, hypotension and vascular collapse; precordial pain, respiratory depression and failure, hyperpyrexia, diaphoresis, and cool, clammy skin.

Treatment Suggestions for Overdose

NOTE: Because there is no recorded experience with selegiline overdose, the following suggestions are offered based upon the assumption that selegiline overdose may be modeled by non-selective MAOI poisoning. In any case, up-to-date information about the treatment of overdose can often be obtained from a certified Regional Poison Control Center. Telephone numbers of certified Poison Control Centers are listed in the Physician's Desk Reference (PDR).

Treatment of overdose with non-selective MAOIs is symptomatic and supportive. Induction of emesis or gastric lavage with instillation of charcoal slurry may be helpful in early poisoning, provided the airway has been protected against aspiration. Signs and symptoms of central nervous system stimulation, including convulsions, should be treated with diazepam, given slowly intravenously. Phenothiazine derivatives and central nervous system stimulants should be avoided. Hypotension and vascular collapse should be treated with intravenous fluids and, if necessary, blood pressure titration with an intravenous infusion of a dilute pressor agent. It should be noted that adrenergic agents may produce a markedly increased pressor response.

Respiration should be supported by appropriate measures, including management of the airway, use of supplemental oxygen, and mechanical ventilatory assistance, as required.

Body temperature should be monitored closely. Intensive management of hyperpyrexia may be required. Maintenance of fluid and electrolyte balance is essential.

DOSAGE AND ADMINISTRATION:

ELDEPRYL® (SELEGILINE HYDROCHLORIDE) is intended for administration to Parkinsonian patients receiving levodopa/carbidopa therapy who demonstrate a deteriorating response to this treatment. The recommended regimen for the administration of ELDEPRYL® (SELEGILINE HYDROCHLORIDE) is 10 mg per day administered as divided doses of 5 mg each taken at breakfast and lunch. There is no evidence that additional benefit will be obtained from the administration of higher doses. Moreover, higher doses should ordinarily be avoided because of the increased risk of side effects.

After two to three days of selegiline treatment, an attempt may be made to reduce the dose of levodopa/carbidopa. A reduction of 10 to 30% was achieved with the typical participant in the domestic placebo controlled trials who was assigned to selegiline treatment. Further reductions of levodopa/carbidopa may be possible during continued selegiline therapy.

Tegretol®

carbamazepine USP

Chewable Tablets of 100 mg—red-speckled, pink   Tablets of 200 mg—pink

WARNING
APLASTIC ANEMIA AND AGRANULOCYTOSIS HAVE BEEN REPORTED IN ASSOCIATION WITH THE USE OF TEGRETOL. DATA FROM A POPULATION-BASED CASE CONTROL STUDY DEMONSTRATE THAT THE RISK OF DEVELOPING THESE REACTIONS IS 5-8 TIMES GREATER THAN IN THE GENERAL POPULATION. HOWEVER, THE OVERALL RISK OF THESE REACTIONS IN THE UNTREATED GENERAL POPULATION IS LOW, APPROXIMATELY SIX PATIENTS PER ONE MILLION POPULATION PER YEAR FOR AGRANULOCYTOSIS AND TWO PATIENTS PER ONE MILLION POPULATION PER YEAR FOR APLASTIC ANEMIA.

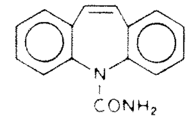
ALTHOUGH REPORTS OF TRANSIENT OR PERSISTENT DECREASED PLATELET OR WHITE BLOOD CELL COUNTS ARE NOT UNCOMMON IN ASSOCIATION WITH THE USE OF TEGRETOL, DATA ARE NOT AVAILABLE TO ESTIMATE ACCURATELY THEIR INCIDENCE OR OUTCOME. HOWEVER, THE VAST MAJORITY OF THE CASES OF LEUKOPENIA HAVE NOT PROGRESSED TO THE MORE SERIOUS CONDITIONS OF APLASTIC ANEMIA OR AGRANULOCYTOSIS.

BECAUSE OF THE VERY LOW INCIDENCE OF AGRANULOCYTOSIS AND APLASTIC ANEMIA, THE VAST MAJORITY OF MINOR HEMATOLOGIC CHANGES OBSERVED IN MONITORING OF PATIENTS ON TEGRETOL ARE UNLIKELY TO SIGNAL THE OCCURRENCE OF EITHER ABNORMALITY. NONETHELESS, COMPLETE PRETREATMENT HEMATOLOGICAL TESTING SHOULD BE OBTAINED AS A BASELINE. IF A PATIENT IN THE COURSE OF TREATMENT EXHIBITS LOW OR DECREASED WHITE BLOOD CELL OR PLATELET COUNTS, THE PATIENT SHOULD BE MONITORED CLOSELY. DISCONTINUATION OF THE DRUG SHOULD BE CONSIDERED IF ANY EVIDENCE OF SIGNIFICANT BONE MARROW DEPRESSION DEVELOPS.

Before prescribing Tegretol, the physician should be thoroughly familiar with the details of this prescribing information, particularly regarding use with other drugs, especially those which accentuate toxicity potential.

DESCRIPTION

Tegretol, carbamazepine USP, is an anticonvulsant and specific analgesic for trigeminal neuralgia, available as chewable tablets of 100 mg and tablets of 200 mg for oral administration. Its chemical name is 5H-dibenz[b,f]azepine-5-carboxamide, and its structural formula is



Carbamazepine USP is a white to off-white powder, practically insoluble in water and soluble in alcohol and in acetone. Its molecular weight is 236.27.

Inactive Ingredients. Colloidal silicon dioxide, FD&C Red No. 3 (chewable tablets only), FD&C Red No. 40 (200-mg tablets only), flavoring (chewable tablets only), gelatin, glycerin, magnesium stearate, sodium starch glycolate (chewable tablets only), starch, stearic acid, and sucrose (chewable tablets only).

CLINICAL PHARMACOLOGY

In controlled clinical trials, Tegretol has been shown to be effective in the treatment of psychomotor and grand mal seizures, as well as trigeminal neuralgia.

It has demonstrated anticonvulsant properties in rats and mice with electrically and chemically induced seizures. It appears to act by reducing polysynaptic responses and blocking the post-tetanic potentiation. Tegretol greatly reduces or abolishes pain induced by stimulation of the infraorbital nerve in cats and rats. It depresses thalamic potential and bulbar and polysynaptic reflexes, including the linguomandibular reflex in cats. Tegretol is chemically unrelated to other anticonvulsants or other drugs used to control the pain of trigeminal neuralgia. The mechanism of action remains unknown.

Tegretol tablets are adequately absorbed after oral administration at a slower rate than a solution, thus avoiding undesirably high peak concentrations. Tegretol chewable tablets may produce higher peak levels than the same dose given as regular tablets. Tegretol in blood is 76% bound to plasma proteins. Plasma levels of Tegretol are variable and may range from 0.5-25 μg/ml, with no apparent relationship to the daily intake of the drug. Usual adult therapeutic levels are between 4 and 12 μg/ml. Following oral administration, serum levels peak at 4 to 5 hours. The CSF/serum ratio is 0.22, similar to the 22% unbound Tegretol in serum. Because Tegretol may induce its own metabolism, the half-life is also variable. Initial half-life values range from 25-65 hours, with 12-17 hours on repeated doses. Tegretol is metabolized in the liver. After oral administration of 14C-carbamazepine, 72% of the administered radioactivity was found in the urine and 28% in the feces. This urinary radioactivity was composed largely of hydroxylated and conjugated metabolites, with only 3% of unchanged Tegretol. Transplacental passage of Tegretol is rapid (30 to 60 minutes), and the drug is accumulated in fetal tissues, with higher levels found in liver and kidney than in brain and lungs.

INDICATIONS AND USAGE

Epilepsy: Tegretol is indicated for use as an anticonvulsant drug. Evidence supporting efficacy of Tegretol as an anticonvulsant was derived from active drug-controlled studies that enrolled patients with the following seizure types:

1. Partial seizures with complex symptomatology (psychomotor, temporal lobe). Patients with these seizures appear to show greater improvement than those with other types.
2. Generalized tonic-clonic seizures (grand mal).
3. Mixed seizure patterns which include the above, or other partial or generalized seizures.

Absence seizures (petit mal) do not appear to be controlled by Tegretol (see PRECAUTIONS, General).

Trigeminal Neuralgia: Tegretol is indicated in the treatment of the pain associated with true trigeminal neuralgia.

Beneficial results have also been reported in glossopharyngeal neuralgia.

This drug is not a simple analgesic and should not be used for the relief of trivial aches or pains.

CONTRAINDICATIONS

Tegretol should not be used in patients with a history of previous bone marrow depression, hypersensitivity to the drug, or known sensitivity to any of the tricyclic compounds, such as amitriptyline, desipramine, imipramine, protriptyline, nortriptyline, etc. Likewise, on theoretical grounds its use with monoamine oxidase inhibitors is not recommended. Before administration of Tegretol, MAO inhibitors should be discontinued for a minimum of fourteen days, or longer if the clinical situation permits.

WARNINGS

Patients with a history of adverse hematologic reaction to any drug may be particularly at risk.

Severe dermatologic reactions including toxic epidermal necrolysis (Lyell's syndrome) and Stevens-Johnson syndrome, have been reported with Tegretol. These reactions have been extremely rare. However, a few fatalities have been reported.

Tegretol has shown mild anticholinergic activity; therefore, patients with increased intraocular pressure should be closely observed during therapy.

Because of the relationship of the drug to other tricyclic compounds, the possibility of activation of a latent psychosis and, in elderly patients, of confusion or agitation should be borne in mind.

PRECAUTIONS

General: Before initiating therapy, a detailed history and physical examination should be made.

Tegretol should be used with caution in patients with a mixed seizure disorder that includes atypical absence seizures, since in these patients Tegretol has been associated with increased frequency of generalized convulsions (see INDICATIONS AND USAGE).

Therapy should be prescribed only after critical benefit-to-risk appraisal in patients with a history of cardiac, hepatic or renal damage, adverse hematologic reaction to other drugs, or interrupted courses of therapy with Tegretol.

Information for Patients: Patients should be made aware of the early toxic signs and symptoms of a potential hematologic problem, such as fever, sore throat, ulcers in the mouth, easy bruising, petechial or purpuric hemorrhage, and should be advised to report to the physician immediately if any such signs or symptoms appear.

Since dizziness and drowsiness may occur, patients should be cautioned about the hazards of operating machinery or automobiles or engaging in other potentially dangerous tasks.

Laboratory Tests: Complete pretreatment blood counts, including platelets and possibly reticulocytes and serum iron, should be obtained as a baseline. If a patient in the course of treatment exhibits low or decreased white blood cell or platelet counts, the patient should be monitored closely. Discontinuation of the drug should be considered if any evidence of significant bone marrow depression develops.

Baseline and periodic evaluations of liver function, particularly in patients with a history of liver disease, must be performed during treatment with this drug since liver damage may occur. The drug should be discontinued immediately in cases of aggravated liver dysfunction or active liver disease.

Baseline and periodic eye examinations, including slit-lamp, funduscopy and tonometry, are recommended since many phenothiazines and related drugs have been shown to cause eye changes.

Baseline and periodic complete urinalysis and BUN determinations are recommended for patients treated with this agent because of observed renal dysfunction.

Monitoring of blood levels (see CLINICAL PHARMACOLOGY) has increased the efficacy and safety of anticonvulsants. This monitoring may be particularly useful in cases of dramatic increase in seizure frequency and for verification of compliance. In addition, measurement of drug serum levels may aid in determining the cause of toxicity when more than one medication is being used.

Thyroid function tests have been reported to show decreased values with Tegretol administered alone.

Hyponatremia has been reported in association with Tegretol use, either alone or in combination with other drugs.

Drug Interactions: The simultaneous administration of phenobarbital, phenytoin, or primidone, or a combination of two, produces a marked lowering of serum levels of Tegretol. The effect of valproic acid on Tegretol blood levels is not clearly established, although an increase in the ratio of active 10, 11-epoxide metabolite to parent compound is a consistent finding.

The half-lives of phenytoin, warfarin, doxycycline, and theophylline were significantly shortened when administered concurrently with Tegretol. Haloperidol and valproic acid serum levels may be reduced when these drugs are administered with Tegretol. The doses of these drugs may therefore have to be increased when Tegretol is added to the therapeutic regimen.

Concomitant administration of Tegretol with erythromycin, cimetidine, propoxyphene, isoniazid or calcium channel blockers has been reported to result in elevated plasma levels of carbamazepine resulting in toxicity in some cases. Also, concomitant administration of carbamazepine and lithium may increase the risk of neurotoxic side effects.

Alterations of thyroid function have been reported in combination therapy with other anticonvulsant medications.

Breakthrough bleeding has been reported among patients receiving concomitant oral contraceptives and their reliability may be adversely affected.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carbamazepine, when administered to Sprague-Dawley rats for two years in the diet at doses of 25, 75, and 250 mg/kg/day, resulted in a dose-related increase in the incidence of hepatocellular tumors in females and of benign interstitial cell adenomas in the testes of males.

Carbamazepine must, therefore, be considered to be carcinogenic in Sprague-Dawley rats. Bacterial and mammalian mutagenicity studies using carbamazepine produced negative results. The significance of these findings relative to the use of carbamazepine in humans is, at present, unknown.

Pregnancy Category C: Tegretol has been shown to have adverse effects in reproduction studies in rats when given orally in dosages 10-25 times the maximum human daily dosage of 1200 mg. In rat teratology studies, 2 of 135 offspring showed kinked ribs at 250 mg/kg and 4 of 119 offspring at 650 mg/kg showed other anomalies (cleft palate, 1; talipes, 1; anophthalmos, 2). In reproduction studies in rats, nursing offspring demonstrated a lack of weight gain and an unkempt appearance at a maternal dosage level of 200 mg/kg.

There are no adequate and well-controlled studies in pregnant women. Epidemiological data suggest that there may be an association between the use of carbamazepine during pregnancy and congenital malformations, including spina bifida. Tegretol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Retrospective case reviews suggest that, compared with monotherapy, there may be a higher prevalence of teratogenic effects associated with the use of anticonvulsants in combination therapy. Therefore, monotherapy is recommended for pregnant women.

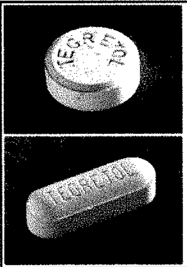
It is important to note that anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

Labor and Delivery: The effect of Tegretol on human labor and delivery is unknown.

Nursing Mothers: During lactation, concentration of Tegretol in milk is approximately 60% of the maternal plasma concentration.

Because of the potential for serious adverse reactions in nursing infants from carbamazepine, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established.



Only TEGRETOL,
brand of carbamazepine,
provides the prescribing
flexibility of a 100-mg scored
chewable tablet, as well as
a 200-mg scored tablet.

ADVERSE REACTIONS

If adverse reactions are of such severity that the drug must be discontinued, the physician must be aware that abrupt discontinuation of any anticonvulsant drug in a responsive epileptic patient may lead to seizures or even status epilepticus with its life-threatening hazards.

The most severe adverse reactions have been observed in the hemopoietic system (see boxed WARNING), the skin and the cardiovascular system.

The most frequently observed adverse reactions, particularly during the initial phases of therapy, are dizziness, drowsiness, unsteadiness, nausea, and vomiting. To minimize the possibility of such reactions, therapy should be initiated at the low dosage recommended.

The following additional adverse reactions have been reported:

Hemopoietic System. Aplastic anemia, agranulocytosis, pancytopenia, bone marrow depression, thrombocytopenia, leukopenia, leukocytosis, eosinophilia, acute intermittent porphyria.

Skin. Pruritic and erythematous rashes, urticaria, toxic epidermal necrolysis (Lyell's syndrome) (see WARNINGS), Stevens-Johnson syndrome (see WARNINGS), photosensitivity reactions, alterations in skin pigmentation, exfoliative dermatitis, erythema multiforme and nodosum, purpura, aggravation of disseminated lupus erythematosus, alopecia, and diaphoresis. In certain cases, discontinuation of therapy may be necessary.

Cardiovascular System. Congestive heart failure, edema, aggravation of hypertension, hypotension, syncope and collapse, aggravation of coronary artery disease, arrhythmias and AV block, primary thrombophlebitis, recurrence of thrombophlebitis, and adenopathy or lymphadenopathy.

Some of these cardiovascular complications have resulted in fatalities. Myocardial infarction has been associated with other tricyclic compounds.

Liver. Abnormalities in liver function tests, cholestatic and hepatocellular jaundice, hepatitis.

Respiratory System. Pulmonary hypersensitivity characterized by fever, dyspnea, pneumonitis or pneumonia.

Genitourinary System. Urinary frequency, acute urinary retention, oliguria with elevated blood pressure, azotemia, renal failure, and impotence. Albuminuria, glycosuria, elevated BUN and microscopic deposits in the urine have also been reported.

Testicular atrophy occurred in rats receiving Tegretol orally from 4 to 52 weeks at dosage levels of 50 to 400 mg/kg/day. Additionally, rats receiving Tegretol in the diet for two years at dosage levels of 25, 75, and 250 mg/kg/day had a dose-related incidence of testicular atrophy and aspermatogenesis. In dogs, it produced a brownish discoloration, presumably a metabolite, in the urinary bladder at dosage levels of 50 mg/kg and higher. Relevance of these findings to humans is unknown.

Nervous System. Dizziness, drowsiness, disturbances of coordination, confusion, headache, fatigue, blurred vision, visual hallucinations, transient diplopia, oculomotor disturbances, nystagmus, speech disturbances, abnormal involuntary movements, peripheral neuritis and paresthesias, depression with agitation, talkativeness, tinnitus, and hyperacusis.

There have been reports of associated paralysis and other symptoms of cerebral arterial insufficiency, but the exact relationship of these reactions to the drug has not been established.

Digestive System. Nausea, vomiting, gastric distress and abdominal pain, diarrhea, constipation, anorexia, and dryness of the mouth and pharynx, including glossitis and stomatitis.

Eyes. Scattered, punctate, cortical lens opacities, as well as conjunctivitis have been reported. Although a direct causal relationship has not been established, many phenothiazines and related drugs have been shown to cause eye changes.

Musculoskeletal System. Aching joints and muscles, and leg cramps.

Metabolism. Fever and chills. Inappropriate antidiuretic hormone (ADH) secretion syndrome has been reported. Cases of frank water intoxication, with decreased serum sodium (hyponatremia) and confusion, have been reported in association with Tegretol use (see PRECAUTIONS, Laboratory Tests).

Other. Isolated cases of a lupus erythematosus-like syndrome have been reported. There have been occasional reports of elevated levels of cholesterol, HDL cholesterol and triglycerides in patients taking anticonvulsants.

A case of aseptic meningitis, accompanied by myoclonus and peripheral eosinophilia, has been reported in a patient taking carbamazepine in combination with other medications. The patient was successfully dechallenged, and the meningitis reappeared upon rechallenge with carbamazepine.

DRUG ABUSE AND DEPENDENCE

No evidence of abuse potential has been associated with Tegretol, nor is there evidence of psychological or physical dependence in humans.

OVERDOSAGE

Acute Toxicity

Lowest known lethal dose: adults, >60 g (39-year-old man). Highest known doses survived: adults, 30 g (31-year-old woman); children, 10 g (6-year-old boy); small children, 5 g (3-year-old girl).

Oral LD50 in animals (mg/kg): mice, 1100-3750; rats, 3850-4025; rabbits, 1500-2680; guinea pigs, 920.

Signs and Symptoms

The first signs and symptoms appear after 1-3 hours. Neuromuscular disturbances are the most prominent. Cardiovascular disorders are generally milder, and severe cardiac complications occur only when very high doses (>60 g) have been ingested.

Respiration. Irregular breathing, respiratory depression.

Cardiovascular System. Tachycardia, hypotension or hypertension, shock, conduction disorders.

Nervous System and Muscles. Impairment of consciousness ranging in severity to deep coma. Convulsions, especially in small children. Motor restlessness, muscular twitching, tremor, athetoid movements, opisthotonos, ataxia, drowsiness, dizziness, mydriasis, nystagmus, adiadochokinesia, ballism, psychomotor disturbances, dysmetria. Initial hyperreflexia, followed by hyporeflexia.

Gastrointestinal Tract. Nausea, vomiting.

Kidneys and Bladder. Anuria or oliguria, urinary retention.

Laboratory Findings. Isolated instances of overdosage have included leukocytosis, reduced leukocyte count, glycosuria and acetonuria. EEG may show dysrhythmias.

Combined Poisoning. When alcohol, tricyclic antidepressants, barbiturates or hydantoins are taken at the same time, the signs and symptoms of acute poisoning with Tegretol may be aggravated or modified.

Treatment

The prognosis in cases of severe poisoning is critically dependent upon prompt elimination of the drug, which may be achieved by inducing vomiting, irrigating the stomach, and by taking appropriate steps to diminish absorption. If these measures cannot be implemented without risk on the spot, the patient should be transferred at once to a hospital, while ensuring that vital functions are safeguarded. There is no specific antidote.

Elimination of the Drug. Induction of vomiting.

Gastric lavage. Even when more than 4 hours have elapsed following ingestion of the drug, the stomach should be repeatedly irrigated, especially if the patient has also consumed alcohol.

Measures to Reduce Absorption. Activated charcoal, laxatives.

Measures to Accelerate Elimination. Forced diuresis.

Dialysis is indicated only in severe poisoning associated with renal failure. Replacement transfusion is indicated in severe poisoning in small children.

Respiratory Depression. Keep the airways free; resort, if necessary, to endotracheal intubation, artificial respiration, and administration of oxygen.

Hypotension, Shock. Keep the patient's legs raised and administer a plasma expander. If blood pressure fails to rise despite measures taken to increase plasma volume, use of vasoactive substances should be considered.

Convulsions. Diazepam or barbiturates.

Warning: Diazepam or barbiturates may aggravate respiratory depression (especially in children), hypotension, and coma. However, barbiturates should not be used if drugs that inhibit monoamine oxidase have also been taken by the patient either in overdosage or in recent therapy (within one week).

Surveillance. Respiration, cardiac function (ECG monitoring), blood pressure, body temperature, pupillary reflexes, and kidney and bladder function should be monitored for several days.

Treatment of Blood Count Abnormalities. If evidence of significant bone marrow depression develops, the following recommendations are suggested: (1) stop the drug, (2) perform daily CBC, platelet and reticulocyte counts, (3) do a bone marrow aspiration and trephine biopsy immediately and repeat with sufficient frequency to monitor recovery.

Special periodic studies might be helpful as follows: (1) white cell and platelet antibodies, (2) 59Fe—ferrokinetic studies, (3) peripheral blood cell typing, (4) cytogenetic studies on marrow and peripheral blood, (5) bone marrow culture studies for colony-forming units, (6) hemoglobin electrophoresis for A_2 and F hemoglobin, and (7) serum folic acid and B_{12} levels.

A fully developed aplastic anemia will require appropriate, intensive monitoring and therapy, for which specialized consultation should be sought.

DOSAGE AND ADMINISTRATION

Monitoring of blood levels has increased the efficacy and safety of anticonvulsants (see PRECAUTIONS, Laboratory Tests). Dosage should be adjusted to the needs of the individual patient. A low initial daily dosage with a gradual increase is advised. As soon as adequate control is achieved, the dosage may be reduced very gradually to the minimum effective level. Tablets should be taken with meals.

Epilepsy (see INDICATIONS AND USAGE)

Adults and children over 12 years of age—Initial: 200 mg b.i.d. Increase at weekly intervals by adding up to 200 mg per day using a t.i.d. or q.i.d. regimen until the best response is obtained. Dosage should generally not exceed 1000 mg daily in children 12 to 15 years of age, and 1200 mg daily in patients above 15 years of age. Doses up to 1600 mg daily have been used in adults in rare instances. ***Maintenance:*** Adjust dosage to the minimum effective level, usually 800-1200 mg daily.

Children 6-12 years of age—Initial: 100 mg b.i.d. Increase at weekly intervals by adding 100 mg per day using a t.i.d. or q.i.d. regimen until the best response is obtained. Dosage should generally not exceed 1000 mg. ***Maintenance:*** Adjust dosage to the minimum effective level, usually 400-800 mg daily.

Combination Therapy: Tegretol may be used alone or with other anticonvulsants. When added to existing anticonvulsant therapy, the drug should be added gradually while the other anticonvulsants are maintained or gradually decreased, except phenytoin, which may have to be increased (see PRECAUTIONS, Drug Interactions and Pregnancy Category C).

Trigeminal Neuralgia (see INDICATIONS AND USAGE)

Initial: 100 mg b.i.d. on the first day for a total daily dose of 200 mg. This daily dose may be increased by up to 200 mg a day using increments of 100 mg every 12 hours only as needed to achieve freedom from pain. Do not exceed 1200 mg daily.

Maintenance: Control of pain can be maintained in most patients with 400 mg to 800 mg daily. However, some patients may be maintained on as little as 200 mg daily, while others may require as much as 1200 mg daily. At least once every 3 months throughout the treatment period, attempts should be made to reduce the dose to the minimum effective level or even to discontinue the drug.

HOW SUPPLIED

Chewable Tablets 100 mg—round, red-speckled, pink, single-scored (imprinted Tegretol on one side and 52 twice on the scored side)

Bottles of 100	NDC 0028-0052-01
Unit Dose (blister pack)	
Box of 100	
(strips of 10)	NDC 0028-0052-61

Tablets 200 mg—capsule-shaped, pink, single-scored (imprinted Tegretol on one side and 27 twice on the scored side)

Bottles of 100	NDC 0028-0027-01
Bottles of 1000	NDC 0028-0027-10
Gy-Pak®—One Unit	
12 bottles—100 tablets each	NDC 0028-0027-65
Unit Dose (blister pack)	
Box of 100	
(strips of 10)	NDC 0028-0027-61

Samples, when available, are identified by the word *SAMPLE* appearing on each tablet.
Protect from moisture.
Dispense in tight container (USP).
Also available as: Tegretol suspension 100 mg/5 ml, in 450 ml bottles.

Books

Neonatal Seizures, edited by Claude G. Wasterlain and Paul Vert, 336 pp, with illus, $98, New York, NY, Raven Press, 1990.

The literature of the epilepsies has burgeoned in the past decade. This is particularly true of pediatric epileptology where basic mechanisms, including molecular biology and genetics; the identification of individual syndromes; and the identification of epileptogenic mechanisms at the neuronal level, the synaptic level, and the higher levels of systems involved in the propagation of the epileptic discharge, have been elucidated.

This book fills a void. Among the identification and classification of epileptic seizures and the epilepsies, knowledge about neonatal seizures has lagged. The lag has been contributed by the difficulty in identifying neonatal seizures, which are frequently subtle and less stereotyped than in the older child, frequently occur in the background of a severe brain disturbance, and depend in their pathophysiology on respiratory and blood flow changes resulting in energy failure in a system with its own fragile autoregulatory mechanisms.

This volume is divided into several sections. These include clinical descriptions of seizures, syndromes, and electroencephalographic changes that bring the patient to the notice of the physician. Basic differences already occur according to the anatomic level of nervous system derangement. The mechanisms of brain damage are discussed at the level of neuronal events, where energy metabolism, selective neuronal vulnerability, and pathologic changes as the result of seizures and status epilepticus are discussed. The metabolism of the immature and neonatal nervous system, the nuances of substrate utilization and blood flow autoregulation, and the use of positron emission tomography and nuclear magnetic resonance imaging in the intact brain are the subject of the next section. A discussion of synaptic events and neurotransmitter pharmacology, including excitatory and inhibitory transmitter mechanisms and the concept of excitotoxins and their consequences, follow. Local circuit changes in specific brain regions, the development of mossy fiber sprouting, and the resulting synaptogenesis and neuronal plasticity involving the molecular layer of the dentate gyrus in experimental epilepsy, are of great current interest and are germane to the evolving rationalization of the therapy of epileptic seizures. The subject of therapy completes the book.

Between the idea and the reality of publication falls the shadow of 3 years in production; yet the volume remains remarkably fresh and current. This book is not just another conference proceeding but represents a major step in illuminating both brain development and the pathophysiology of epilepsy. It is highly recommended to all who strive to better apply the results of neuroscience research to understanding the compromised developing nervous system and translating this understanding to improving rational therapies.

Fritz E. Dreifuss, MB, FRCP, FRACP
Charlottesville, Va

Amyotrophic Lateral Sclerosis. Concepts in Pathogenesis and Etiology, edited by Arthur J. Hudson, 378 pp, $75, Toronto, Ontario, University of Toronto Press, 1990.

This book is a collection of 15 papers presented in 1987. Contributors include the editor, Dr Arthur Hudson, who is the founder of the Amyotrophic Lateral Sclerosis (ALS) Society of Canada, and Drs Antel, Calne, Dalakas, Eisen, Gajdusek, Hirano, Kurland, and others who have been important, long-time students of ALS and other neurodegenerative disorders. The interest of the presentations ranges broadly. This is a sampling of observations put forth in some of the reports: "Use of cultured human fetal spinal cord neurons currently represents the most promising model system in which to explore the cause of ALS." "Sera from a proportion of patients with ALS and other denervating diseases produce a . . . decrease [sic] of motoneuron death during embryonic development." "Classic ALS . . . apparently results in impaired metabolism of gangliosides, which leads to rapid death of motor neurons." "Understanding of the molecular basis of the retrovirus-induced motor neuron disease in mice . . . we hope will help to [prevent and treat human neurodegenerative diseases]." "The . . . data indicate a failure as yet to detect unique antibodies interacting with motor neurons in ALS." Motor neuron diseases "clinically indistinguishable [from classic sporadic ALS] include familial ALS, Western-Pacific ALS, post-encephalitic ALS, and a presumably infective form of disease [following a cat bite]."

A special feature of this volume is the considerable attention paid to the Western-Pacific form of ALS and its changed incidence as well as its controversial link to dietary habits.

The book is well presented, with care unusual for the product of a symposium. Some of the discussions, such as that concerning the pathologic basis of the disease, are very useful resources that should outlive the usual lifespan of this type of collection. To read this book is to gain some assurance that those of us who are practicing last-century medicine in caring for our patients with ALS have reason to hope that the treatment of the disease will move into the modern era. The hopefulness that this creates in practitioners cannot help but reach our patients and their families. It is clear that the investigators who compiled this book have that ultimate objective in mind.

David Goldblatt, MD
Rochester, NY

Imaging of the Nervous System, by Paul Butler, 271 pp, with illus, $198, New York, NY, Springer-Verlag Inc, 1990.

This book presents a well-written overview of the imaging modalities of the central nervous system. Computed tomographic scanning, magnetic resonance imaging, angiography, myelography, plain-film radiography, duplex sonography, and isotope imaging are discussed; the primary emphasis is on computed tomographic and magnetic resonance imaging. The first chapter discusses cerebrovascular disease with an excellent review of the pertinent findings of cerebral infarction on computed tomography. The pattern of attenuation and enhancement, hemorrhage, mass effect, vascular territory, age of the infarct, and the differential diagnosis are covered in depth. The difficult subject of discussing the varied causes of cerebrovascular disease is concisely handled. Other well-written chapters discuss intracranial tumors, hydrocephalus and degenerative diseases, trauma, infections, pediatric neuroimaging, spine imaging, orbit imaging, temporal bone imaging, the muscular and peripheral nervous system, and isotope imaging.

The text is well organized and is concisely written. The information is practical, current, and well referenced. The printing is legible, the legends are informative, and the illustrations are of high quality.

The need for a concise up-to-date summary of central nervous system imaging is well fulfilled by this book. Although this book is useful to all radiologists, neurologists, and neurosurgeons, it is especially well suited for residents in training. In addition, this text would serve as an excellent reference in medical libraries for medical students and practicing physicians and surgeons.

STEPHEN E. JOY, MD
Rochester, NY

Essentials of Child Neurology, by Suresh Kotagal, 192 pp, $42, St Louis, Mo, Ishiyaku EuroAmerica Inc, 1990.

Essentials of Child Neurology is another in the recent spate of minitextbooks on pediatric neurology. As stated by the author in the preface, this book attempts to provide an intermediate-length summary of the discipline.

The book's chapters vary from topic-oriented to symptom- or sign-oriented and provide succinctly written summaries of major problems in clinical pediatric neurology. The book begins with a brief introduction to the neurologic history and the examination of the infant and young child, emphasizing the developmental factors that influence neurologic findings. Chapter 1's section, "Commonly observed Neurological Manifestations," represents a useful glossary of neurologic terms. Inclusion of concise definitions of neurologic jargon is a laudable feature throughout the text.

Subsequent chapters cover numerous topics in pediatric neurology, including infections of the central nervous system, seizure disorders, neurocutaneous syndromes, neuromuscular conditions, and neurodegenerative disorders, to name but a few. Most information is accurately presented, and the book contains sufficient detail regarding contemporary therapeutic modalities for many disorders. The well-written chapter describing sleep disorders as well as the chapters on seizure disorders and neurologic emergencies provides practical information relevant to residents and practitioners.

The book does a commendable job of incorporating information regarding developmental disabilities and school failure, topics that are frequently considered on the fringe of traditional pediatric neurology. By contrast, tumors of the nervous system and the neurologic complications of systemic illnesses receive only cursory mention. Readers would be well served by additional material regarding neoplasms of the central nervous system and the expanding role for chemotherapy in the treatment of such tumors.

Although the chapters per se are generally well organized and include an introductory outline, the sequencing of chapters could be improved. The chapter describing "Common Neurodiagnostic Procedures" would more logically follow the chapter on "Clinical Assessment," and the nicely written chapter on "Neonatal Neurology" could be juxtaposed with the section describing the "Development of the Nervous System and its Aberrations." The text could also indicate more clearly the relative prevalence of disorders that constitute a specific differential diagnosis.

The book contains several tables and algorithms that appropriately supplement material in the text. Certain tables, particularly those summarizing central nervous system storage disorders and hereditary neuropathies, incorporate abundant, valuable clinical details. In general, the algorithms provide useful information regarding the formulation of a differential diagnosis. Each chapter concludes with a modest number of references or suggestions for further reading.

A few publishing glitches detract from the overall quality of Dr Kotagal's effort. The type seemed a bit fuzzy in places, and some illustrations lacked clarity or were off-center. The book sent for review was missing pages 25 through 32, an error hopefully limited only to this copy. Occasional typographical errors, eg gentamycin and ethosuxamide, were also detected. Despite these flaws, *Essentials of Child Neurology* achieves its goal and constitutes a readable, introductory-level text suitable for students, residents-in-training, and many practitioners.

Delirium: Acute Confusional States, by Z. J. Lipowski, 490 pp, $69.50, New York, NY, Oxford University Press, 1990.

Delirium is an erudite, comprehensive treatment of a difficult yet important subject. Z. J. Lipowski deserves credit for bringing together many areas of widely discrepant opinions, descriptions, and explanations for the complex phenomena that can be observed in acute confusional states or delirium. As there is a great deal of variability in symptomatology, delirium is a difficult problem to study. The patients are usually quite ill, uncooperative, and difficult to examine, and the phenomena of delirium is transient. All of this explains the scarcity of systematized research and the abundance of anecdotal descriptions. Delirium is one of the few abnormal mental phenomena that has been experienced by almost everyone. Most of us have gone through a febrile state in childhood with vivid, dreamlike hallucinations and remember the horrifying experience.

The definition of delirium to encompass all forms of confusional states will not sit well with everybody. Most people would define the term *delirium* to be an acute confusional state with restless and excited behavior. This argument over terminology is reflected in the lengthy chapters on the history of delirium and the definition of terms. The definition of delirium in the *Diagnostic and Statistical Manual of Mental Disorders*, third edition (*DSM III*), is overinclusive and nonspecific at the same time and is not very helpful in defining this common and characteristic clinical phenomena. It would not be the first time that attempts by a few experts from "above" failed to match the general usage, and it would not be the first time a pedantic definition in the *DSM III* turned out to be inadequate shortly after it was written. There are plenty of reasons to object to lumping patients with reduced alertness and decreased psychomotor activity into the category of delirium, which is distinguished by increased verbal, psychomotor, and autonomic activity. The author himself lists a number of these. The usefulness of this distinction should be evident to most of those who have been called on to diagnose the cause of confusion in a febrile child, an alcoholic, or in one who overdosed on drugs. I suspect that this distinction will continue to be used and remain important, despite efforts by the author and others to consider it a manifestation of delirium.

In the description of symptoms, one cannot help but think that some of these represent different disease processes at one time or another. For example: "As the severity of delirium grows, the patient becomes increasingly distractible and either drowsy and lethargic or hyperalert and agitated . . . . Concurrently, thinking becomes increasingly labored and slow or rapid, but incoherent." The overinclusive descriptions are not very useful, such as "the speed, frequency, and loudness of vocalization are often increased or decreased in delirium. Speech is absent on occasion and the patient is mute. At the other extreme, a ceaseless flow of speech, often repetition of the same words or phrases, tends to be part of a general overactivity." Surely such widely discrepant phenomena represent different origins and different mechanisms. In a comprehensive book such as this, one would expect more emphasis on specificity and analysis rather than generalization. The author seems to have left out the interesting phenomena of reduplication and the Capgras syndrome. I could not find any listing for these in the index.

The descriptive chapter on hallucinations and their psychopathology is well done. Recent knowledge concerning serotonin metabolism in dreams and drug-induced hallucinations and some of the studies concerning the primary visual nature of hallucinations are interesting. On the other hand, disorders of memory are reviewed somewhat superficially. The chapter on predisposing and facilitating factors and etiology is well organized. Particularly extensive is the review of sleep-deprivation studies. The treatment of delirium is well referenced and is one of the most useful chapters in the first part of the book.

The second part of *Delirium* deals with the more specific causes of this disorder, the most important one being drug intoxication. I think this is one aspect of clinical medicine that is relevant to almost all disciplines. The important concept of confusional states as a cognitive, attentional disturbance, induced by cholinergic blockade, is expanded in the chapter on anticholinergic toxicity. Cholinergic deficiency may be a common denominator in many other metabolic toxic encephalopathies that produce a reduced rate of acetylcholine synthesis.

The section on toxic substances is brief and will require the reader to use the references extensively for more specific information. Alcohol is given the substantive treatment it deserves. The chapter on metabolic encephalopathies and infections is fairly current and even includes the acquired immunodeficiency syndrome. However, it does not deal specifically with herpes simplex encephalitis, which must be one of the most specific causes of treatable confusional states. This chapter only mentions the periodic complexes in relation to herpes. One would like to have seen the differential diagnosis and a description of neuroimaging and treatment.

This is a useful book for any physician's library, and I expect that in the future I will make frequent use of it myself. It is particularly recommended for neurologists, internists, psychiatrists, and specialists in intensive care medicine.

Lesion Analysis in Neuropsychology, by Hanna Damasio and Antonio R. Damasio, with illus, $42.95, New York, NY, Oxford University Press, 1989.

The lesion method in studying brain-behavior relationships has had a stormy history. The excellent book by Hanna and Antonio R. Damasio should greatly strengthen the value of this method. As I looked over the excellent brain images with their accompanying neuroanatomical templates, one could wistfully hope that Broca could see what he started.

The Damasios, cognizant of the classic contributions and knowledgeable from their own extensive research, do not make the errors that have plagued neuropsychology and have eroded the value of the lesion method. They remind us again of some fundamental concepts and give illustrative case histories to buttress these concepts. First, they emphasize, as did Hughlings Jackson, that the loss of a function with a specific lesion does not mean the construct for that function resided there. Second, they note that only with careful testing and breaking down a response to its component parts can we understand what role the lesion played in its disruption—a lesson taught us by Luria. Third, they dispel the notion that associating a syndrome with a lesion does not mean that there is necessarily some common feature to all elements of the syndrome. This was a lesson learned from their great teacher, Arthur Benton, who critically analyzed the Gerstmann syndrome. Fourth, they avoid the mistake of pre-World War II neurologists who made inferences from well-described single anatomicoclinical case reports and post-World War II psychologists who described extensive series of patients without good anatomic descriptions. They use multiple single case reports combining the best of the well-described single case and the value of a series of patients. Fifth, they do not make the mistake of assuming all of us have similar wiring diagrams unaffected by experiences, language formation, and other subtle factors, so that behavior may vary from patient to patient with similar lesions.

The methods portion illustrates the painstaking work that is necessary to produce their discrete lesion localization. This, combined with their testing methods, have contributed greatly to our understanding of many different clinical entities, such as prosopagnosia, aphasias, memory problems, and others.

The theoretical portion introduces some novel concepts. The authors reject the notion that bilateral lesions of the multimodal sensory cortices destroy perceptual experience. They introduce the concept of "convergence zones." Essentially, they build their theory on my view of the justification of a neuroanatomy course, "Everything in the brain is connected to everything else—unfortunately, some of the connections have names." They suggest on the basis of their studies that multiple regions of the brain cooperate in a reciprocating fashion, both anterograde and retrograde, to create an internal representation of the stimulus in a convergence zone. Not only does their work buttress this notion, but recent electrophysiological findings of widespread synchronization of neural regions to a stimulus suggest wide and diverse participation in sensory interpretation.

The last part of the book is an elegant description, along with examples, of the methods of localization largely developed by Hanna Damasio. The advantages and pitfalls of her method are fully discussed.

The contribution of these two investigators to the field of brain-behavior linkages are immense. They have again demonstrated that the lesion method is the major means of understanding brain function.

Letters to the Editor

Letters to the editor should be submitted as an original and two duplicates. They should be typewritten double-spaced on plain bond paper; they will be subject to editing. If they are prepared on a word processor, do not justify the right margin. A copyright transmittal letter signed by all authors must accompany this (see "Instructions for Authors").

Magnetic Resonance Imaging Hyperintensities in Alzheimer's Disease

To the Editor.—This letter is a commentary on Leys and coworkers' article in the May 1990 issue of the ARCHIVES.[1] We commend Leys and coworkers on their effort to determine the significance of white matter and periventricular changes in patients with Alzheimer's disease. The pathological significance of these changes are particularly difficult to assess since, as Leys and coworkers indicate, they are found in many neurologically and psychiatrically normal controls. However, we feel that several methodological issues may make it difficult to generalize the findings in this study. First, the authors excluded 11 of 31 subjects due to poor quality in magnetic resonance imaging scans. They were not clear why more than one third of the patients with Alzheimer's disease had technical difficulties in imaging. We agree with the authors' concern that exclusion on the basis of an inability to cooperate with the magnetic resonance imaging scan may have lead to a skewing of the sample toward healthier patients with Alzheimer's disease. The relatively small magnet size and large interslice gap of 6 mm would also have made their detection of white matter lesions less sensitive.

Second, the authors are not clear why they rate an interobserver agreement on all original 42 subjects since they described technical problems in the scans of 11 subjects. These poor-quality scans would probably have been more difficult to read and have lowered the interobserver agreement. Poor interobserver agreement clearly is a concern when judging the accuracy of the data.

Third, the authors' conclusion that there was no correlation noted between age or Mini-Mental Status Examination and periventricular hyperintensities may be due to the relatively small sample size and narrow age range of their subjects. A number of studies have shown that white matter changes occur with increased frequency in "normal" aging (eg, Drayer et al[2]), and data from our group using 39 normal control subjects confirm this finding with subcortical hyperintensities.[3] The fact that there was no age correlation may indicate that the age range of their subjects was too narrow.

Fourth, the authors failed to mention whether the subjects had a history of mood disorders. This would have been interesting since white matter disease has been found in increased frequency in patients with late-onset depression[4] and late-onset mania.[5]

Finally, the authors mix early- and late-onset patients with Alzheimer's disease, although there is evidence that these may represent two distinct patient groups.[6]

The use of neuroimaging in the workup of the demented patient continues to be a necessary and important tool. Continued study of the significance of white matter and periventricular lesions is essential in this process.

To the Editor.—In an imaging study of Alzheimer's disease and normal aging, Leys et al,[1] using our rating scale,[2] found no difference in magnetic resonance imaging white matter hyperintensities between the two groups, and only *a trend toward increased periventricular hyperintensity in patients with Alzheimer's disease.* This is in contrast to our initial observation of a hyperintense "halo" in six of 12 cases of Alzheimer's disease.[2] We would like to emphasize, however, that a part of us (F.F., R.S., H.O.) could not replicate this finding in a subsequent study performed under similar conditions. There still remains a trend toward more signal abnormalities in Alzheimer's disease, however. The Table summarizes the current data from subjects without cerebrovascular risk factors in this ongoing project.[3]

A disproportionately higher number of patients with more marked ventricular enlargement in our first study appears to be the likeliest explanation for these discordant findings, since we observed a close correlation between ventricular size and the periventricular hyperintensity area by planimetric analysis (unpublished results). Similar findings to that of Leys et al were also reported by another group pursuing a similar study design.[4]

We are in agreement with Leys et al in terms of imaging findings, but would like to challenge their comments on the usefulness of our scoring scheme:

1. It appears inappropriate to include scans that are technically inadequate for data analysis in a calculation of interobserver agreement. Movement artifacts will strongly obscure border zones such as the periventricular area, and interpretation of small

Prevalence of Magnetic Resonance Imaging Hyperintensities in Study Population Without Cerebrovascular Risk Factors

	Alzheimer's Disease	Control Subjects
Number	16	13
Mean age, y	66 ± 7	64 ± 8
White matter hyperintensities		
None	5	7
Punctate	8	5
Early confluent	3	1
Periventricular hyperintensity		
None	2	6
Caps and/or "lining"	12	7
"Halo"	2	0

punctate foci of increased signal will become quite arbitrary.

2. An uneven level of magnetic resonance imaging interpretation skills among observers with a different background may negatively affect interobserver agreement as well. Kozachuk et al[4] achieved a considerably better interrater reliability with our scoring scheme, reporting a κ coefficient of 0.80 for periventricular hyperintensity and of 0.64 for white matter hyperintensities when scans were interpreted by neurologists only.

3. A simple scoring scheme such as ours will be more likely to yield good interobserver agreement than a complex one. In addition, although Leys et al imply that the more elaborate leukoaraiosis-computed tomographic rating system[5] might be more sensitive to intergroup differences, they present no data to support this.

In conclusion, we think that Leys and coworkers' observation of a minor role of white matter hyperintensities and periventricular hyperintensities in patients with Alzheimer's disease without cerebrovascular risk factors represents a true finding but does not reflect inadequacy of the scoring scheme.

In Reply.—The significance of white matter and periventricular hyperintensities and the question whether they differ between patients with Alzheimer's disease and age-matched controls remains to be discussed. We found no difference between patients with Alzheimer's disease and normal subjects.[1] Fazekas and McDonald point out possible methodological bias we would like to discuss in the following nine points:

(1) We agree with them that including magnetic resonance imaging scans of lower quality for calculation of interobserver agreement might have lowered κ values in the evaluation of Fazekas' scoring system.[2] We have again calculated κ among the 27 high-quality magnetic resonance images and we found very small improvements (periventricular hyperintensity, 0.44 instead of 0.43; white matter hyperintensity, 0.58 instead of 0.50). Kozachuck et al[3] found higher values of κ than we did but most of their subjects had very low periventricular and white matter hyperintensity scores; we think that the interobserver reliability is more likely to be lower among subjects with such low scores. We have just finished (publication in process) a new study in 29 patients with Alzheimer's disease and 34 control subjects with high-quality magnetic resonance imaging to evaluate the intraobserver and interobserver reliability of a more elaborate rating scale. All magnetic resonance imaging scans were scored independantly by four of us (D.L., J.P.P., P.S., F.B.) using both rating scales; we compared them using Bland and Altman's method.[4] This study confirmed the poor intraobserver and interobserver reliability of Fazekas' scoring system and a moderate superiority of our new rating scale in spite of its complexity.[2] (2) An uneven level of magnetic resonance imaging interpretation skills among observers with different backgrounds may effectively have affected intraobserver and interobserver agreements in our study. In our new study the magnetic resonance imaging evaluations were performed by two neuroradiologists and two neurologists; the intraobserver agreements were better with radiologists (J.P.P., F.B.) but they did not significantly differ from those of neurologists (D.L., P.S.). (3) Fazekas' opinion that their simple scoring system will be more likely to yield good intraobserver and interobserver agreements than a complex one is not confirmed in our new study. Moreover, in a study of computed tomographic white matter changes in Alzheimer's disease,[5] we found a high level of intraobserver ($\kappa = 0.95$) and interobserver ($\kappa = 0.88$) agreements using the very elaborate scoring system of Rezek et al.[6] (4) We totally agree with Fazekas' opinion that observations of a minor role of white matter and periventricular hyperintensities in patients with Alzheimer's disease without cerebrovascular risk factors represent a true finding and do not reflect inadequacy of the scoring scheme. When our study was published, we were unable to affirm this, but now we have further information in accordance with Fazekas' opinion: in order to know the role of the scoring scheme, two of us who were not coauthors of the article (P.S., F.B.) reinvestigated, in another European University Hospital, our magnetic resonance imaging using their own scoring method[7] and they confirmed the lack of difference between patients with Alzheimer's disease and control subjects. (5) The reason why one third of subjects had technical difficulties in imaging is related to their neuropsychological impairments, since this was observed only in the group with Alzheimer's disease. This undoubtedly has led to a skewing of the population toward less affected subjects as suggested by McDonald; the mean Mini-Mental State Examination scores in this study were significantly higher than in other studies performed by our study group.(6) We agree with McDonald's opinion that possible problems secondary to small magnet size and large interslice gap might have occurred. However, the technique was the same between the two groups, and if we could have missed some hyperintensities, it would be balanced between groups. Of course, new generations of machines will avoid such problems in the future. (7) None of the 27 subjects included in the study had a history of mood disorders, according to a comprehensive discussion with a close relative. (8) We also agree with McDonald's opinion that we probably found no correlation between white matter and periventricular hyperintensity scores and Mini-Mental State Exami-

nation scores in patients or age in normal subjects since we have patients with high mean Mini-Mental State Examination scores. In our further study with 63 subjects, with larger ranges of Mini-Mental State Examination scores and ages, we found: (1) in control subjects a correlation between periventricular and white matter hyperintensity scores and age, and (2) in patients no correlation between periventricular and white matter hyperintensity and Mini-Mental State Examination scores, as reported by Kozachuck et al.[4] (9) McDonald's question whether early- and late-onset Alzheimer's disease might represent two different groups according to magnetic resonance imaging white matter changes cannot be answered from our recently published study,[1] since it included 14 patients with presenile Alzheimer's disease and only three patients with senile Alzheimer's disease. This question was recently investigated in our new study in 34 control subjects and 29 patients, all free of any possible vascular risk factor. We confirmed all our previous data, but only in presenile Alzheimer's disease (onset before age 65): we found no difference between patients with Alzheimer's disease and control subjects for both white matter and periventricular hyperintensities (16 patients with Alzheimer's disease and 15 control subjects; beta risks of type II errors, 0.15 and 0.03). However, in senile subjects (13 patients with Alzheimer's disease and 19 control subjects) white matter hyperintensities were significantly higher in Alzheimer's disease ($P < .01$; Mann-Whitney U test). Like us, Kozachuck et al[4] found no difference between patients and control subjects, and they probably have a predominance of presenile cases too, according to the mean ages of their patients. These new data point out the necessity to look at the mean age of the study population, and that matching patients and control subjects might not be sufficient. The age of the study population and whether they have senile or presenile dementia might have more importance than the scoring scheme to explain differences between the results of different studies.[7]

We are grateful to Fazekas and McDonald and their coworkers to give us the opportunity to discuss this point.

Third-Nerve Palsies and Angiography

To the Editor.—Aneurysmal compression of the third nerve produces an oculomotor nerve palsy with prominent pupillary involvement. Cerebral angiography is indicated in the workup of such third-nerve palsies if another cause is not promptly forthcoming. *Pupil-sparing* third-nerve palsies are often caused by local ischemia, and the risks of angiography are likely increased in such individuals. Unfortunately, occasional third-nerve pareses with limited pupillary participation *do* result from early aneurysmal compression,[1] presenting the clinician with a management dilemma.

A noninvasive test that could eliminate aneurysmal compression as the cause of a third-nerve palsy would be most valuable. Currently, lack of spatial resolution compared with conventional angiography and slow flow within the aneurysm preclude magnetic resonance angiography from replacing conventional angiography in the diagnosis of small cerebral aneurysms.[2] However, aneurysms that produce oculomotor nerve palsies should be relatively easy to detect: their sites of involvement are known and they are usually larger than 4 mm.[3]

Our recent experience with two patients who had acute third-nerve palsies involving the pupils is not encouraging. Spin echo magnetic resonance imaging and magnetic resonance angiography were performed using flow-related enhancement. The magnetic resonance angiography was acquired with the following techniques: TR = 52 milliseconds/TE = 11 milliseconds and a flip angle of 90° on a Philips 1.5 tesla magnet. Slice thickness was 3 mm, with a 1-mm overlap. The images were reformatted to three-dimensional images. Pre-excitation was used to suppress signal produced by flow in the opposite direction. We were unable to detect the anticipated posterior communicating artery aneurysms, which proved to be 5 and 6 mm in diameter at conventional angiography.

Magnetic resonance imaging of patients with third-nerve palsies will detect many of the causative aneurysms, but, at present, normal magnetic resonance imaging studies cannot rule out aneurysmal compression of the third nerve.

Editorial

Freeze the Ocean

The *Journal of the American Medical Association* and its family of specialty journals are addressing the issue of access to medical care. Matthew Menken presents a thoughtful look at this problem in a special article in this issue.[1] One of the major priorities in most industrialized nations is the provision of universal access to high-quality medical care at low cost. There have been varying degrees of success and many failures, and an ideal program has not been found. Certainly, the system in the United States has failed as there are millions of citizens who are underinsured or poorly insured. Basic desiderata just mentioned fall apart when other elements are deemed important, as instant and convenient access to care, free choice, unrationed care, finest technology, and adequate reimbursement for the providers (hospitals, physicians, nurses). There is then a trade-off, and, unfortunately in this country, it is universal access. Also, as Menken points out, the care even when available may not serve the patient's needs.

See also p 472.

The medical care in the United States when at its best is likely unparalleled anywhere in the world. Certainly, it is the most expensive by far. But consistently, in surveys done in industrialized countries of the world, we are the least satisfied with our health care system.[2] The dissatisfaction does not arise from the quality of care but from the fear that we may not have the insurance or sufficient insurance when it is required. A fear that is not shared with citizens of other countries surveyed.

The Canadian system of health care has the highest satisfaction rating by its own citizens. It is also the system most admired by United States citizens. Even in Britain, which has the lowest cost per capita for health care, the satisfaction rate is higher than in this country.

At this time when we are critically evaluating our own system with the possibility of more government involvement, both the Canadian and British systems are showing major stresses.

The Canadian government through the provinces is the single payer. The Canadian system saves a significant portion on administrative costs and global hospital budgeting.[3] Payment to individual physicians is less, but disparity in income is not great as overheads due to billing costs and malpractice insurance are considerably less.[4] Our idyllic view of the health system north of the border is now being questioned as more and more stresses appear in the Canadian system.[5] Long waits for services, inconvenient services, inadequate access to technology, lack of innovative delivery systems, and provider discontent are parts of the complaint. The transplantability of the system is also questioned, often along culture lines. A Canadian health official pointed out that Americans were paranoid about their government in that they did not trust it; on the other hand, the Canadians are schizophrenic in that they had a greater trust in government but felt the government went about it all wrong. However, there are many excellent features of their system such as global budgeting of hospitals and greater control of placement of expensive technology.

The British National Health System, again with universal access, has a fundamental difference from the Canadian system. The National Health System became both payer and provider by nationalizing the hospitals and employing the physicians. The system has evolved and has been modified since its inception in 1948. During the Thatcher years it came under increasing scrutiny, and in 1989 a government White Paper recommended major reforms.[6] Many of the proposed reforms had the government lessening its control over hospitals and practitioners. What will evolve from this is yet to be seen, but major concerns about restriction in services have already arisen.

No system seems to have the perfect solution as Menken, quoting Mencken, suggests in his special article.[1] It is likely that we all know what is needed and desirable. We can land a man on the moon and put a bomb down a chimney from 10 000 feet, but these projects pale when we deal with the multifarious and diverse elements of the health care system. We are in the situation of the admiral who was asked what to do about the U-boat threat. He replied immediately, "Freeze the ocean. Those on the top can't go down, and those on the bottom can't come up." When asked how this would be accomplished, he replied, "I just set the policy, you work out the details." It is the details that will be difficult.

Caring for the Underserved

Health Insurance Coverage Is Not Enough

Matthew Menken, MD

The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research stated in 1983 that "Society has a moral obligation to ensure that everyone has access to adequate care without being subjected to excessive burdens."[1] By this measure, the health system of the United States is failing, since millions of citizens are unable to obtain necessary care each year. This is a paradox, given the large annual medical care expenditures in the United States. In 1991, such expenditures will exceed $600 billion, or 11.5% of the gross national product, an average of $2500 per capita. Comparative health care figures reveal that the United States spends per capita 38% more money than Canada, 88% more than West Germany, and 124% more than Japan. Moreover, expenditures in the United States are rising rapidly. Between 1980 and 1987, health expenditures in the United States increased from $248 billion to $500 billion, an increase of 102% during this brief period.[2]

See also p 471.

I suggest that the proportion of the gross national product now spent on health care in the United States is probably more than sufficient to provide comprehensive care for all people, including the provision of effective and high-quality medical care for those people presently underserved.[3] No other country has such readily available technology, an equivalent density of well-trained physicians in 24 specialties, or the institutional resources needed for first-rate medical care. American biomedical and health services research is generally acknowledged to be a bigger and better enterprise than anywhere else. A major deficiency is the system's failure to provide care for approximately 37 million people, or 15% of the population, who are unable to afford private insurance and are also ineligible for publicly funded programs.[4] Contrary to popular belief, nearly three fourths of these uninsured citizens are working Americans and their families, and more than two thirds are white. Only 40% of all of our citizens below the poverty level (including many children) are insured through Medicaid, a program ostensibly designed for the poor. Given this disturbing evidence, it is not surprising that public opinion polls find many US citizens dissatisfied with their health care system. There is little doubt that health care access and cost are the major issues of concern for most of these Americans.

BARRIERS TO ACCESS

Since cost is only one of the barriers to access for high-quality care, the total number of underserved people greatly exceeds the number of uninsured and underinsured. For example, many health indicators demonstrate a disparity among people of different racial and ethnic groups that cannot be ascribed entirely to cost. In 1987, the age-adjusted death rate for stroke among the black population was nearly twice that of white people, while the infant mortality rate for black infants (17.9 per 1000 live births) was more than twice the rate for white infants (8.6 per 1000 live births). About 79% of white mothers began prenatal care in the first trimester, compared with 61% of black and American Indian mothers.[5]

Such data suggest that, although cost is an important barrier to health care for many Americans, other access barriers may be paramount for some people. For example, geographic barriers are important for many rural families. In 1985, there were 53 physicians per 100 000 people in US counties whose total population was less than 10 000, compared with a national average of 165 physicians per 100 000 people. Geographic and language barriers, and the "culture of poverty," are also important problems in access in blighted urban areas where the mortality rate for adult black men exceeds that of some developing countries. Between 1963 and 1980, office-based physicians in such urban areas declined 45%.[6] With the exception of some adult and pediatric training programs in hospitals that emphasize culturally appropriate care, there is a consensus that inner-city hospital–based care is often more impersonal and less culturally sensitive than office-based care, especially when such care is provided by minority physicians.[7]

Furthermore, medical care is only one factor in the determination of health status, which also depends on many other sociocultural parameters. Sanitation, the quality of the food supply, the level of education in the community, among other factors, influence personal health status. If medical care were the only determinant of health, and cost the only access barrier, then one would anticipate that a cost-free health care system, as under the National Health Service in

the United Kingdom, would demonstrate health status equality for all population groups. Many studies in the United Kingdom conducted over two decades have demonstrated a robust negative association between social class (often called socioeconomic status in the United States) and all-cause mortality.[8] The lower the social class, the greater the mortality. This remarkably consistent finding occurs at all levels of society, and it is not limited only to those people who are overtly poor and deprived. For example, individuals in upper managerial roles and their families have a lower rate of all-cause mortality than do those in middle-management roles and their families. The same negative correlation has been observed for many medical and neurological disorders such as coronary artery disease, stroke, and many forms of cancer.[9]

Such data suggest that solving the problem of caring for the "uninsured and underinsured," although certainly of great importance, is not coextensive with the larger and more difficult task of caring for the underserved, as might be implied by the rubric of this theme issue of the ARCHIVES under which this article is subsumed. The conventional wisdom notwithstanding, individual physicians and the American Medical Association should make it clear to policymakers that insurance reform and financial measures alone, now as in the past, will likely fail to solve the twin societal goals of caring for the underserved and further improving care quality. In 1929, when national expenditures of $3.6 billion, or $30 per capita, were already a source of great public concern, the prestigious Committee on the Costs of Medical Care discovered "much waste" in such features of the health system as payments for ineffective medications, uncoordinated private practices, and inefficiently used hospitals. This Committee called for changes in the organization and patterns of delivery of medical care as the appropriate way to control costs, ". . . in view of the widespread lack of needed medical care. . . ."[10]

It remains unchanged after more than half a century that many factors that contribute to differences in health status as a reflection of the social stratification of society and the material aspects of living, such as housing, education levels, and working conditions, are not readily influenced by medical interventions, however accessible. The same public resistance to provide necessary resources for neuroscience research and the medically underserved applies also in the case of the nutritionally underserved, the housing underserved, and the educationally underserved. There are an estimated 2 million homeless people in the United States, and 20 million illiterate adults. For these people, a more humanitarian system of financing medical care would obviously be beneficial, but much more needs to be done. Clearly, the mitigation of poverty (especially child poverty), homelessness, and social deprivation can contribute greatly to improved national health indicators and the relief of human suffering. Given the focus of national attention on the cost of care, it should be underscored repeatedly that caring for the underserved and caring for the uninsured and underinsured are qualitatively different conceptualizations for public policy.

CARING FOR THE UNINSURED AND UNDERINSURED

Given the multifaceted and labyrinthine problems of the underserved, it is not surprising that proposals to mitigate the lack of health insurance abound, whereas the broader care crisis among the underserved has received much less attention.[11] It seems likely that even these more limited proposals will face rough sailing in the political arena. On July 1, 1988, President Reagan signed the Medicare Catastrophic Coverage Act of 1988, the largest expansion of federal involvement in health care since 1965, when the Social Security Amendments of 1965 (Medicare and Medicaid) were first implemented. Unlike prior policy that paid for coverage out of general tax revenues, the 1988 law required that the wealthier beneficiaries pay an income tax surcharge, and that all beneficiaries pay an additional $4 in the basic Medicare part B monthly premium. Although mandated benefits under this law were quite generous, the constituency of the American Association of Retired Persons opposed this measure vigorously. Fearing political fallout, Congress hurriedly repealed the law altogether, leaving those senior citizens without supplementary private insurance more vulnerable than ever to increasing medical bills.[12]

The many proposals for improving insurance coverage reflect a consensus that something needs to be done, but a controversy about what to do.[13,14] A proposal by Physicians for a National Health Program calls for a national health insurance program modeled on the system in Canada, with a single public insurance payor for all health care, and a predetermined annual cap on payment to hospitals.[15] Another proposal, the Consumer Choice Health Plan, would convert all insurance plans to prepaid coverage, and would require employers to purchase insurance for employees' health care from competing managed care plans.[16] The National Leadership Commission on Health Care proposal would provide health care for the uninsured through a state-based program funded by government, employers, and beneficiaries (on the basis of income), and would include an expanded technology assessment and outcome evaluation effort.[17] The American Medical Association has presented a 16-point proposal, *Health Access America*, that includes reform of Medicaid, Medicare, and professional liability, also requires employer provision of health insurance, and would create state-run risk pools for the uninsured.[18]

CARING FOR THE UNDERSERVED

H. L. Mencken is reputed to have said that for every complex human problem there is a solution that is simple, elegant, and wrong. What is generically problematic with many proposals for health system reform is a viewpoint sharply focused on health insurance and cost. This focus on selected aspects or abstractions of an actual situation or problem, while ignoring other factors of relevance, is an example of a common source of logical error in many scientific fields, which has been called the Fallacy of Misplaced Concreteness.[19] I would suggest that the American Medical Association's framework for change is exceptional and noteworthy, in part because it lends itself more readily than most other proposals to such structural and procedural changes in the delivery of medical services as may be needed to provide better care for the underserved. Caring for the uninsured and underinsured is an important first step, but equity and social justice in health care also require caring for all of the underserved. As an additional step toward resolution of this problem, I would propose the following measures as ones that merit thoughtful and open-minded discussion.

First, efforts to improve the scientific underpinning of medical care must be expanded, as a logical step toward prevention of disorders that rely for treatment on expensive "halfway" interventions. For example, it has been estimated that mortality from metastatic female breast cancer can be reduced 30% by regular breast examination and mammography performed at recommended intervals.[20] Moreover, about 30% of total Medicare hospital expenditures are on behalf of patients in the last year of life, mostly the last 6 months, many of whom suffer from Alzheimer's disease and other dementias. Given the large cost of services for patients with dementia, and a prevalence of Alzheimer's disease of nearly half of all people older than 85 years of age (the most rapidly growing segment of the US population), it is astonishing that research funding for this disorder amounts to only 0.15% of the costs of care.[21,22]

Although *Health Access America*, the AMA's health care proposal, correctly calls for the expansion of biomedical research, a broader paradigm of research is necessary to provide comprehensive care for the underserved. As I have suggested previously, amplification of the investigative effort should logically include much more research in the social and behavioral sciences relevant to human health and disease,[23] as well as an expanded health services research agenda to foster intersectoral cooperation with workers in such fields as nutrition, education, and housing.[24] Such health services research activity in the recent past has included an expanded effort to measure the appropriateness and effectiveness of medical care, an examination of health system administrative costs and the effects of reimbursement reform, as well as "the technology of patient experience" (outcomes research), as in the recent initiatives of the American College of Physicians and the Public Health Service's Agency for Health Care Policy and Research.[25-27]

Second, the absolute number and relative proportion of primary care physicians must be expanded. The President of the Association of American Medical Colleges has noted that ". . . our academic medical centers will lose vital national and public support if they do not respond to society's desire for more primary care physicians."[28] Of all physicians in the United Kingdom, Canada, and the United States, 70%, 50%, and 30%, respectively, are generalists. In my view, solving the crisis in primary care is an essential component of any solution to the problem of caring for the underserved in the United States. Put another way, most of the care requirements of the underserved fall within the domain of primary care medicine. Hence, providing adequate insurance for all people cannot be expected to correct the mismatch between actual health needs and the specialty distribution of physicians. This keystone issue is one that often goes unnoticed or unsupported by many neurologists and other specialists. It is a question of our orientation and commitment to provide high-quality medical care for individual patients, without a concomitant awareness of those people who are not receiving care, as well as the differential burden of illness in the entire population to be served. This is an example of what has been called the *Inverse Care Law*, which holds that market forces cause medical care to vary inversely with the need for it in the population to be served.[29]

What is needed to address this issue, first of all, is a major initiative to recruit minority health professionals and strengthen minority medical institutions. Among 15 433 senior medical students in 1989 through 1990, only 826, or 5.3%, were black. (As of September 1, 1989, there were only 29 black neurology residents on duty, including one child-neurology resident.) Moreover, special measures are needed to recruit talented students from rural and other underserved areas, since these individuals are more likely to establish primary care practices where they are most needed.[30] Perhaps it is time to reform the criteria by which candidates are selected for enrollment in medical school. Each medical school might set its own arbitrary *threshold level* of academic grades and examination scores that all candidates must surpass, but once that is done, grades and scores no longer matter in the selection process for those individuals who exceed the cutoff level.[31] Finally, is there any doubt that the framework for physician payment and professional liability needs to be modified so that doctors can care for the underserved without great risk to their personal and family's financial security?

Third, medical schools need to develop appropriate community-oriented learning experiences for all medical students. In terms of faculty prestige and status, students learn that the "ins" are in (hospital based), and the "outs" are out (ambulatorium). Some schools have experimented with educational programs in health maintenance organizations, community health centers, and other facilities. It is also a question of decentralizing a health system that preferentially directs resources to surgical and procedural interventions carried out in hospitals, leaving community-based and preventive services seriously underfunded. Given the widespread dissatisfaction of many people with the health system, and the declining number of applicants to American medical schools, health science centers need to identify the task of medicine, in its broadest sense, for all students and residents, as well as the role of the doctor in an industrialized society. We seem to have forgotten that scientific expertise and technical competence are not the foundations of patient satisfaction in many situations. When learning is exclusively carried out in teaching hospitals, students sometimes get the erroneous impression that caring is what is left for doctors to do when curative medicine has failed.

In terms of caring for the underserved, learning experiences in the community will heighten student and resident awareness of local priority health problems based on sound epidemiological principles, as in the educational model developed by an international task force commissioned by the Network of Community-Oriented Educational Institutions for Health Sciences.[32] Such "real life" experiences, in which students live and learn in selected community settings, are likely to foster the linkage between knowledge and skills, on the one hand, and the concept of social responsibility, on the other, so that all students understand why the social role of every doctor, regardless of the field of specialization, must extend beyond the care of individual patients.

CONCLUSIONS

In May 1977, the Thirtieth World Health Assembly resolved that "the main social target of governments and the World Health Organization in the coming decades should be the attainment by all citizens of the world by the year 2000 of a level of health that will permit them to lead a socially and economically productive life."[33] To achieve this goal in the United States, expanding insurance coverage for the uninsured and underinsured is an important step. However, the many barriers to care other than cost, and the limited role of medical care as a determinant of the overall health status of the population, call for a more comprehensive framework for reform that views health care for all of the underserved in its social context.

I suggest that the proposal of the American Medical Association, *Health Access America*, might be modified and enlarged to address these concerns. The expansion of the biomedical research agenda should be matched by a much larger research effort in the social and behavioral sciences relevant to human health and disease, as well as the health services research agenda. The mismatch between the specialty distribution of physicians and the health needs of the entire population to be served calls for an increase in the number and proportion of primary care physicians, and the recruitment of a larger number of minority medical students. Finally, all medical students should have active learning experiences in a community-oriented framework of service provision to ensure that future generations of physicians understand the role of medical care for population groups as well as individual patients. Together, such changes signify the addition of relevance to the equation of access, cost, and quality in caring for the underserved.

Access to Health Care

One Neurologist's Perspective

Michael P. Earnest, MD

• Millions of residents of the United States have difficulty obtaining health care. Barriers impeding access to care include poverty, physical unavailability of health care services, absence of health insurance, and physicians unwilling to care for uninsured patients. Many patients do not successfully use health services because of educational, cultural, and language barriers. A major access barrier is lack of health insurance. Over 30 million people in the United States have none, the so-called medically indigent. Among them are over 3 million people with neurologic disorders. They have additional barriers to overcome because often they cannot work, cannot drive, have difficulty using public transportation, and have major cognitive and communication impairments. Medical and governmental bodies are debating solutions to the health care access crisis. Physicians should actively participate in this national debate. Neurologists should address the special needs of patients with neurological disorders.

(*Arch Neurol.* 1991;48:476-479)

A 52-year-old laborer had a long history of poorly controlled hypertension. A stroke at age 40 years caused a mild left hemiparesis, but he was able to continue working parttime and he was fully independent in his daily living. He had no health insurance and no savings. He had last seen a physician at a public clinic but admitted he had not taken the antihypertensive medications that had been prescribed. He admitted to prior heavy alcohol use but denied any alcohol use since the stroke.

Three days before his admission on December 5, 1990, while at home, he had sudden vertigo, nausea, and vomiting and then fell. He could not recall subsequent events but was found 48 hours later still on the floor, conscious but confused and unable to get up because of a severe left hemiparesis. He was taken by ambulance to a private hospital, where he was treated in the emergency department. A computed tomographic scan showed an old right-sided cerebral infarct. Twelve hours later, he was transferred to Denver (Colo) General Hospital and was admitted. The patient stated he was transferred because "I didn't have any money."

During this hospitalization, he was in the intensive care unit 18 days for management of severe hypertension, aspiration pneumonia, respiratory failure, recurrent chest pain, and thrombophlebitis. He had a gastrostomy because of dysphagia and aspiration. After 30 days, he was transferred to the rehabilitation unit. The total bill for the 30 days was $61 185.

Five weeks later his left arm remained totally paralyzed. He could take a few steps using a walker and a leg brace and with assistance. He was still fed by gastrostomy. He remained in the rehabilitation unit. He was not expected to return to work and so had applied for welfare assistance and Medicaid. The rehabilitation staff expected he would have to stay at least several weeks in a nursing home. He hoped eventually to resume independent living and to be able to swallow food again.

Many residents of the United States have difficulty obtaining needed health care (Table 1).[1,2] Growing concern about barriers between patients and health care has prompted numerous governmental and medical reports on inadequate access to health care, the effect of this on health status, and possible solutions to the problem.[3-6]

FACTORS AFFECTING ACCESS TO HEALTH CARE

An individual's access to health care depends on several interrelated factors that fall into the following four principal categories: financial, health care system, personal/cultural, and social system.[7,8] The financial determinants of access to care are health insurance (eg, private or employer-based insurance or Medicare/Medicaid coverage) and personal cash reserves to pay the expected bills, medication prescriptions, and related costs, including transportation. Access to the health care system is determined by the physical availability of a physician, clinic, or hospital[6] and the capacity or willingness of those providers to see the patient. Personal and cultural determinants of access are the characteristics of the patient that enable successful acquisition of health care services. Education, ability to speak and read English, attitude toward health and health care, and cognitive ability are all important. Social system access to Medicaid or other public assistance programs for health care depend on availability of state and federal programs and accessible entry systems, including local offices.

A sick person can obtain health care services if there is a physician's office or other health facility available, the patient has sufficient insurance or cash, is motivated to seek care, and can communicate with the provider about the illness. However, multiple barriers pre-

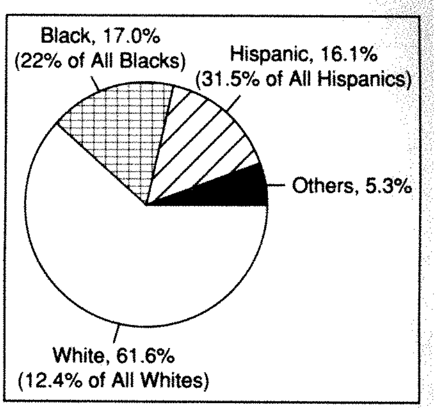
Table 1.—Percentage of 10 130 Respondents Reporting Difficulty Obtaining Health Care*

Type of Difficulty	%
People with chronic or serious illness who had no physician visit in prior 12 months	18.5
Needed care but had difficulty obtaining it	16.1
Pregnant women without care in first trimester	15.8
Economic barriers to receiving health services	7.8
Tried to get care but could not, for financial reasons	0.4

*Adapted from Robert Wood Johnson Foundation Special Report.[1]



Uninsured US population by race (from King[3]).

vent many US citizens from receiving needed care. Poverty, lack of health insurance, absence of physicians and clinics in rural and inner-city areas, low level of education, inability to speak or read English, and intimidating health system and social services bureaucracies all create barriers between many people and health care.[1,7-10]

People with neurological disorders may have even more difficulty obtaining health care than do others. The author's clinical experience in an urban municipal hospital indicates that patients with dementia, stroke, Parkinson's disease, multiple sclerosis, and epilepsy have special problems obtaining health care. Those diseases often cause loss of jobs, inability to obtain health insurance, problems driving a car or using public transportation, and impaired mental and communication ability, all of which interfere with obtaining health care. Public assistance programs, such as Medicaid, offer only partial relief of the financial problems, but the other problems remain formidable.

THE NATIONAL PROBLEM OF MEDICAL INDIGENCY

Because the United States has no universal health insurance system, individuals here must pay for medical care through personal health insurance or with out-of-pocket cash. Absence of health insurance is a major barrier to obtaining health care in our nation.[1,3,6,9,11] More than 30 million people under the age of 65 years have no health care insurance.[3,11] Estimates of this "medically indigent" population are as high as 37 million, about 15% of the US population.[3] This group has substantially increased during the last two decades.[1,3,11] Over half of these people are employed or are dependents of full-time employees; many others are the poor who are not eligible for Medicaid.[3,11] About 62% are non-Hispanic whites, 17% are black, and 16% Hispanic (Figure).[3,12] Ten million of the medically indigent are under the age of 19 years.[3]

Why do so many people have no health insurance? Federal and state health insurance systems cover many segments of the population. Medicare covers those over 65 years old and some chronically disabled people. Medicaid covers many impoverished pregnant women, mothers with dependent children, and most impoverished chronically disabled adults. However, state-funded Medicaid programs do not cover many people below the poverty level.[3,5] Also, many young people just entering the work force have no insurance for themselves or for their families.[3] Because of high premium costs, many employers, especially small and service-industry companies, offer no health insurance benefits.[3,11] Self-employed workers can purchase insurance, but many cannot afford the high price. All of these gaps in health insurance coverage combine to create the huge medically indigent population.

A consensus is growing among political and medical leaders that the absence of health insurance prevents people from receiving needed health care.[1,3,6,13] Long-term effects of reduced access probably are higher morbidity and mortality for uninsured people.[14,15] The excess morbidity and mortality increase unemployment and increase expenditures of public funds for the health-impaired population.[13] Widespread lack of health insurance is a major economic issue, not just one of social justice.

NEUROLOGIC DISORDERS AMONG THE MEDICALLY INDIGENT

The prevalence and incidence of neurological disorders among the medically indigent have not been studied. Kurtzke[16] estimated that neurologic disorders affect about 9.5% of the entire US population, ie, a point prevalence rate of 9500 per 100 000. Extrapolating that figure to the 34 million medically indigent, 3.2 million people have neurologic disorders. Using his estimates for prevalence of specific disorders, 272 000 people have cerebrovascular disease or transient ischemic attacks, 221 000 have epilepsy, 100 000 have lumbosacral herniated disk, 85 000 have cerebral palsy, 85 000 have dementia, and 68 000 have Parkinson's disease. Using Kurtzke's annual incidence figure, 850 000 medically indigent people develop a neurologic disorder within a given year.[16] Many of those patients need both acute and continuing neurological care.[17]

An additional large but unquantified number of cases of the acquired immunodeficiency syndrome (AIDS) exist among the medically indigent, and the prevalence of cases is still increasing. Employed people with AIDS eventually lose their jobs and then their health insurance, becoming medically indigent. Neurologic complications occur in over half of the people with AIDS,[18] so neurologic consultations, computed tomographic and magnetic resonance scans of the brain, and other neurologic tests often are needed.

NONFINANCIAL BARRIERS TO HEALTH CARE

Regardless of employment and insurance status, many patients in rural areas and in large inner-city poverty tracts have no access to care because physicians, clinics, and hospitals are not located there. Those patients must travel longer distances and incur higher costs in transportation and time to seek medical care. The physical and cognitive disabilities associated with neurologic diseases create even more problems traveling to distant clinics. The poor face other important access barriers.[7-10] Limited education, especially about health, leads to delay in seeking acute care, inattention to preventive services (eg, detection and treatment of hypertension to prevent stroke), and noncompliance with medical instructions and medication usage. Language barriers interfere with access for Spanish-speaking, Asian, and other non–English-speaking patients. Cultural values that deny illness or values that emphasize traditional healing methods may interfere with proper use of available medical care. The high prevalence

Table 2.—Features Common to Many Proposals for Providing Health Insurance to All US Citizens

Expand Medicaid to include the poor currently not covered
Mandate that employers provide health insurance to all employees
Establish state insurance "pools" to cover those "uninsurable" because of severe medical conditions
Develop insurance to pay for catastrophic illness and long-term care

of alcohol and other substance abuse and of severe mental illness in inner-city poor populations compounds the educational and cultural factors.[19]

Even middle-class, educated, insured patients are facing more barriers to neurologic care. Managed-care systems, trying to limit utilization and hold down costs, discourage primary care physicians from referring patients to specialists (eg, neurologists) and from ordering expensive tests, including computed tomographic and magnetic resonance scans. Hospital admissions are being limited by utilization-review plans and lengths of hospital stay controlled by diagnosis related group reimbursement. How much these mechanisms deny access to needed health services is unclear. Nonetheless, even though the purpose may be laudable, they are barriers between patients and health care services, including neurological services.

WHO TREATS THE ACCESS-POOR PATIENTS?

Most patients with limited access to medical care are treated in public clinics and hospitals and in urban teaching hospitals, both public and private. The "general hospital" and its clinics have long been the "safety net" for meeting health needs of the urban Medicaid and uninsured population.[6,20] However, these facilities are under extreme financial and political pressure.[21,22] Emergency departments, clinics, and wards are strained to the point that an acceptable quality of care often is compromised.[6] Reduced reimbursements from Medicaid, increasing numbers of uninsured patients, the epidemics of AIDS, drug abuse, and violence in the inner cities, and increased hospital operating costs have driven many public and private teaching hospitals deeply into debt.[21,22] Some have even closed.[21,23] Those that remain open are short-staffed and overcrowded.

Physicians in their private offices and hospitals have traditionally cared for many Medicaid and medically indigent patients. However, inadequate Medicaid and other governmental reimbursement, rising overhead costs, fear of malpractice liability and decreased ability to shift costs from the "no-pay" to the "full-pay" patients have forced private physicians and hospitals to reduce charity care. Now, they give emergency care and then arrange further treatment at a public agency,[21,24] the practice commonly termed "dumping."

With the private sector giving less charity care and the public sector unable to keep up with the increasing demand, indigent patients suffer even more. In the author's hospital and clinics, waiting times for visits have increased, heavy patient copayments have been instituted (eg, $250 for elective surgery), clinic hours have been reduced, and, now, discussion of reducing or even discontinuing major services has begun (eg, pediatrics and mental health). These steps are intended to increase revenues and decrease expenses, but they all create further barriers to access.

PROPOSALS TO SOLVE THE NATIONAL HEALTH CARE CRISIS

Numerous reports and plans have been published by governmental commissions, private study groups, and medical associations proposing steps to resolve the health care access crisis.[3-6,13,25-27] Several features are common to many proposals (Table 2). First, they propose that the Medicaid program should be expanded to cover all people below the federal poverty level who currently are uninsured. The uninsured poor with incomes above the poverty level could enroll in Medicaid by paying a graduated premium based on income. Second, the working uninsured would be covered by employer-sponsored health insurance. Small business employers would be given tax incentives, thus reducing their cost for providing insurance. Third, state-sponsored insurance pools would cover the "uninsurable" population, people with chronic costly diseases who cannot obtain insurance and who also are not eligible for Medicaid. Finally, long-term care and catastrophic illness coverage would be provided.

Other proposals advocate a federal government–sponsored national health insurance plan, possibly based on the Canadian health insurance system.[28] Several states, among them Massachusetts, Hawaii, and New York, have established statewide universal health insurance plans.[29] Some proposals advocate community action and more donated charity care by hospitals and physicians.[30,31]

In spite of the numerous commissions, studies, and proposals, major obstacles to any national solution exist. The first is the extraordinarily rapid growth in costs of health care and the corresponding growth of health care insurance premiums. Expenditures for health care in the United States grew from $75 billion in 1980 to nearly $500 billion in 1987 (*Am Med News.* Jan 12, 1990:25-26).[32] Health care expenses escalated from 7.4% of the gross national product in 1970 to 11% in 1988. Any solution to the health insurance crisis must include provisions to pay for implementing the plan and must include steps to restrict the rapid growth in health care costs. Illustrating the costs involved, expansion of the federal Medicaid program to cover the currently uninsured poor would cost between $9 and $35 billion, the exact amount depending on the services covered and the population included.[33]

Efforts to curb costs include "rationing" or "prioritizing" care by setting limited benefit packages,[13] requiring patient copayment, imposing managed care plans in which primary care providers act as "gatekeepers" between patients and high-cost care, and second opinions for high-cost procedures. Unfortunately, these cost-cutting measures are also barriers between a patient and health services.

The problem of cost also leads to contradictory public opinions about health care. Polls indicate that we want everyone, even the poor, to have access to health care (*Am Med News.* July 27, 1990:6).[34,35] We also want access to the latest, most expensive tests and treatments. Yet we do not want increased taxes or cuts in nonhealth programs to pay health care costs for the medically indigent (*Am Med News.* July 27, 1990:6).[34,35]

Even if a comprehensive nationwide health insurance plan were enacted, other access barriers would remain. Limited access would persist because of inequitable distribution of health providers and because of the educational, cultural, and social factors.

WHAT CAN PHYSICIANS DO?

Individual physicians cannot solve the health care access problems for over 30 million uninsured or for the comparably large Medicaid population. However, a physician can treat an individual person who needs care. Physicians in private practice, especially specialists (eg, neurologists) who may only need to perform a diagnostic consultation and then see the patient again a few times, can help by accepting uninsured and Medicaid patients. The editor of the *Journal of the American Medical Asso-*

ciation encouraged such professional commitment.[30] Physicians who work in municipal hospitals, public clinics, and teaching hospitals can help by continuing to provide as much high-quality, readily accessible care as is possible. Private and public physicians alike can urge administrators and boards of their hospitals and clinics to remain fully available and responsive to the needs of patients who come for care. At the same time, all physicians can limit health care costs for individual patients, and collectively for all of society, by charging reasonable fees, ordering tests prudently, and managing cases in a cost-effective fashion.

At the community level, physicians and medical societies can donate services to public clinics and hospitals. They can establish voluntary free clinics to give care to people with no other resources. They can work with community groups concerned about the problems of medical indigency, long-term care, cost of health care, and related issues.[31] Neurologists can advocate, with special authority, provision of services for people with chronic neurologic impairments, especially those in the medically indigent population.

On the state and national levels, organized physician associations can educate legislatures and governmental agencies about the health needs of the indigent and recommend programs to improve access to health care. Specialty societies, including neurologic societies, can develop plans focused on the needs of their specific patients. They can publicize those programs through the press and their own publications. The American Medical Association, American Society of Internal Medicine, American Academy of Pediatrics, and American College of Physicians, among others, have developed specific proposals.[4,5,7,26,36,37] The American Academy of Neurology has created a Task Force on Access to Health Care to study access and economic issues for patients with neurologic disorders.[38] Professional associations can also speak out on behalf of adequate funding for the health care agencies that provide care to the indigent and Medicaid populations.

COMMENT

Access to health care has become more difficult for tens of millions of people in the United States, many of whom cannot obtain needed health care. More than 3 million among that population have neurologic disorders. The long-term consequences of inadequate access to care cannot be predicted, but clinical common sense and available research studies indicate that the consequences will be higher morbidity and mortality in the medically indigent population. Exploding costs and widespread opposition to spending more on health care both preclude "quick-fix" solutions to the problem. Many different proposals have been made, and state legislatures and Congress are debating the issues.

Under any future national health plan, physicians will provide the health care. We should take an active part in the national debate on access to that care. Neurologists should speak out for the needs of patients with neurologic disorders, including the special needs of those among the medically indigent.

My thanks to L. P. Rowland, MD, New York, and J. A. Cohen, MD, Denver, Colo, for helpful comments and to Denise Lovato for preparing the manuscript.

Access to Neurological Care for Minorities

Edgar J. Kenton, MD

• Minority groups comprise a major segment of the estimated more than 34 million Americans without insurance coverage and also the underinsured. Neurologic disease and neurologic complications of the major causes of morbidity and mortality affect minorities protracted by limited access to health care. Hypertension, a major cause of stroke in the black population, is just one example of the impact of accessibility to intervention in central nervous system disease. Health statistics note the persisting gap between minority groups and the nation's norms for life expectancy. Aging America and particularly black elderly women, combined with the lagging infant mortality among minority groups, demonstrate limited access issues beyond economics, reflecting inner city mores, cultural barriers, and communication delay limiting contact with the practicing neurologist. Awareness of such access limitations to neurological care for minorities demands the attention of the practicing neurologist and the neurological societies.

(*Arch Neurol.* 1991;48:480-483)

Many reports in recent medical and lay literature cite increasingly limited access to our health care system by minority populations. The American College of Physicians, the nation's largest medical specialty society, published a position paper in 1990 calling for a nationwide program to improve access to health care for all Americans.[1] They cited the growing number of Americans without access to health care. It is well documented that access to health care is dependent on one's socioeconomic level and also minorities comprise the majority of the lower socioeconomic scale.[2-4] It follows that limited access to health care affects many minority groups seeking care. Minorities comprise a large component of the estimated 34 to 37 million Americans under age 65 who have no health care insurance.[5] Furthermore, life expectancy among many minority groups has declined in recent years. Mortality rates among the poor and disadvantaged are higher for most causes of death as are prevalence rates of major disabilities including heart disease, cancer, and stroke.[6,7]

Practicing neurologists can attest that complications of heart disease, cancer, and stroke damage the central nervous system. Early intervention can prevent or reduce the severity of those disorders; limited access to medical attention probably accentuates severity. To disadvantaged minorities, neurologic symptoms and signs as well as the discipline itself are enigmas. They may refuse a lumbar puncture for fear of paralysis or fear of spreading the malady, or equate multiple sclerosis with muscular dystrophy or defer a computed tomographic scan or magnetic resonance imaging of the brain for fear of brain injury. Others fail to initiate or maintain medication due to cost.

The incidence of stroke has declined 60% over the past three decades, yet such cannot be stated at a similar rate in minorities.[8] There has been little impact on mortality during the initial 3 days following stroke onset and only a slight improvement in the 30-day mortality rate.[9] Studies have been reported by the National Cancer Institute, the National Minority Health Association Inc, the National Medical Association, and the Urban League, citing the relation of limited access for health care among minorities.[10-13] Hypertension, heart disease, and atherosclerosis are the major factors influencing stroke and are clearly related to access issues. Illustrating the gravity of the current situation, Charles Francis, MD, Director of Medicine, Harlem Hospital, New York, NY, reported on the crises of compliance with antihypertensive medication in the inner city[14] and indicated that hypertension control rates among Harlem patients have fallen from more than 80% to only 50% over the past several years.

Statistics, however, suggest neurologic complications of the leading mortality causes affecting minorities may, indeed, be remedial as attempts are being made by many medical organizations to improve access to health care. The National Center for Health Statistics revealed the average life expectancy in 1988 that for blacks was 69.2 years and for whites, 75.6 years.[15] From 1984 through 1988, the gap between life expectancies for whites and blacks increased from 5.6 years to 6.4 years. However, the year 1989 showed a distinct improvement in life expectancy for the population as a whole over 1988 and in blacks' life expectancy, despite a 32% increase in deaths from human immunodeficiency virus infection and an increase in homicides in the United States. Death rates for cerebrovascular diseases, heart disease, and atherosclerosis were less in 1989 than in 1988; heart disease, stroke, and cancer all showed a decline in mortality compared with those in the previous year. Statistics suggest neurologic complications of such major mortality and morbidity issues, contributors to significant components of the nation's health care costs, demand our attention in removing existing barriers of access to neurological care for minorities.

While the uninsured and the underinsured face socioeconomic barriers inhib-

iting access to neurological care, there are other minority-based issues that restrict access. As discussed by the several articles in the recent *JAMA* issue on Hispanic health in the United States, there is high minority density in the inner cities where few private doctors and clinics are available and primary health care is provided by overcrowded emergency rooms and public clinics.[16] Those initial lines of medical defense usually do not address the many subtleties of neurologic diagnoses, nor do they provide continuity of care often required in neurologic management, for example, continuing treatment of epilepsy. Generations of minorities distrust such facilities, often remembering the bad experiences of their ancestors; and tradition dies hard.

In addition, many minority senior citizens supported by Medicare and adequate supplementary insurance could afford a private doctor. But often they are admitted from emergency rooms to the teaching services as unassigned patients to be followed thereafter by residents in the outpatient clinics and not as private patients. Thus, they have limited access to more experienced physicians, are exposed to the resident rotation system, and are relegated to a system usually established for the underinsured. Also, how many minority patients have the resources required to secure disability benefits for chronic neurologic impairment from a complex, uncaring, and bureaucratic social services system? They often need legal assistance. Many minority stroke patients with diagnosis related group–limited hospital stay would rather return to the supportive familiarity of the home and family, but cannot because of working spouses or children. Indeed, many minority individuals with primary neurologic illness such as transient ischemic attacks, "mini strokes," multiple sclerosis, disabling peripheral neuropathies, and spondylitic spastic paraparesis never see a neurologist, preferring the continuity of the family physician over the impersonal public clinic or hospital.

To limit access discussions to economic issues and insurance coverage, therefore, avoids historically inculcated and culturally ingrained ingredients that impair utilization of neurologic services. Minorities, regardless of economics, because of their limited contact with physicians of their own background and because of the low rate of preventive physical examinations, such as recommended by the US Preventive Services Task Force, continue to lag behind the nation's norms in access to all health care, including neurologic care.[17] To the extent that acculturation succeeds through education, job opportunities, social and community action programs, and physician participation will access to health care proceed.

The Medicare/Medicaid programs, created in the mid-1960s, produced significant improvement in the health status of minorities. However, those same populations continue to lag behind the white population not only in infant mortality but also in life expectancy of its senior citizens affected by stroke, Parkinson's disease, and dementia.[18,19] *JAMA*, in its issue focusing on minority health, highlighted a 1986 survey on the utilization of health services. That survey demonstrated significant lack of access to health care among black compared with white Americans experienced at all socioeconomic levels. Also, blacks compared with whites were less likely to be satisfied with the quality of physician care and hospital care, and they were more likely to believe length of stay too short.[20-22]

Hypertension, a leading cause of stroke in minorities, seriously impacts on neurologic care. Numerous studies[23-25] reveal that approximately 28% of adult blacks suffer from hypertension compared with about 17% of adult whites and that blacks develop hypertension at a younger age than do whites. Advanced hypertension is five times more common in blacks. Stroke mortality in blacks is 65% higher than that in whites. Black persons with hypertension probably are more susceptible than are hypertensive whites to the neurologic complications of the disease. Yet, according to the *JAMA* articles, whites and blacks respond similarly to antihypertensive therapy, achieving control at about the same numbers.[26] Yet, minority populations do not receive antihypertensive therapy to the same degree as the white population because of access-limiting costs of drugs, continuity of care, early intervention, and education of drug effects. The implications of such limited access to antihypertensive regimens can be seen in such reports by Francis[14] and others[27-30] revealing deteriorated health care for minorities and contributing to end-stage disease.

Other studies have shown that the delay from onset of symptoms for stroke to arrival at the hospital[31] was markedly prolonged for minorities compared with predominantly white populations.[13] The same is true for the latency period from arrival at the hospital to neurologic consultation for minorities, if such consultation is obtained at all.

The "graying" of America is one of the most significant demographic barriers to neurologic care access. Current national population projections indicate that the number in all age categories of 60 years will be considerably larger at the end of this century and will continue to grow for the first three decades of the 21st century. The black elderly are the most economically disadvantaged of any of the minority groups. The black elderly are more likely to be sick and disabled with higher rates of hypertension, cerebrovascular disease, cardiogenic stroke, spondylitic paraparesis, peripheral polyneuropathy, and dementia. Elderly black women are revealed by studies to be the most apt to be living alone, relying on increasingly shrinking access to and availability of our nation's home health care providers.[32]

Recognizing these factors of minority-based health care that contribute to neurologic complications, what is the role of the neurologist in easing access to neurological care? Minorities experience complex health disadvantages related to poverty, disinformation, and racial bias, limiting access to quality health care. However, neurologists first and foremost must be aware of these issues. If we wish to implement the plan proposed by the National Advisory Neurological Disorders and Stroke Council of the National Institute of Neurologic Diseases and Stroke for the "decade of the brain," the issues of access to health care become fundamental for enabling such efforts.[33] Louis Sullivan, MD, Secretary of Health and Human Services, stated that what we do now in areas of prevention will pay off well into the 21st century and that our health, its maintenance, and prevention of disease have become a high priority in the black community.[34]

Matthew Menken, in his editorial in the November issue of the ARCHIVES, concerning the practice of neurology, commented that "As an educational tool the anecdotal method assumes that the practicing physician who is roughly right is preferable to one who is precisely wrong."[35] The wealth of anecdotal experience of practicing neurologists in both the public and private sectors who deal with minority health care indicates that access to neurological care is an important health care issue. Minority patients with stroke, epilepsy, cerebral palsy, dementia, developmental disability, head trauma, and neurological complications of acquired immunodeficiency syndrome need neurological consultations and may need computed tomographic scans or magnetic resonance imaging and then continuing, long-term management. The personal experience of the author and other neurologists[36] indicates that minorities have difficulty obtaining neurologic care. Precise data on the extent of the problem for neurological patients are not available. However, the national problem for minority patients overall is well documented and the problem demands corrective action. Our specialty organizations must mobilize the support and the participation of neurologists in practice to address the chief complaints of the minority community in their quest for access, ie, how to obtain quality neurologic care. The symptoms and signs of access malady must be addressed, ie, problems that minority groups have communicating with providers of neurologic care, plus limited education especially about health, impeding disease detection and prevention, and culturally based lack of motivation to seek help. Many community resources should be utilized to help solve the problem including minority churches, social organizations, and political groups. Practicing neurologists and our specialty societies can develop studies such as conducted by the Robert Wood Johnson Foundation[5] and the Massachusetts Institute of Technology, Cambridge, Mass,[37] and can stimulate activities by private foundations in their community.[38,39] The American Academy of Neurology has established a task force on access to neurologic care.[35] We, as neurologists, must heed the call of the minority community and provide the availability of neurologic care.

Blacks constitute 12% of the population, 4% of doctors under age 40, and only 2.5% of neurology residents in the 1980s.[40] What can and should the neurologic societies do about such disturbing numbers? Programs should be developed in coordination with the task force on access to neurological care, educating its members in such issues. Programs can be provided addressing neurological problems of minorities for presentation to the minority communities in detection and early intervention strategies. High school student programs in minority communities dealing with neurological issues can be highly effective in recruiting medical school applicants. Neurological societies can also encourage minority medical student applicants for currently available student training grants in neurological research. What can individual neurologists do in addition to becoming more aware of this enormously complex issue? In addition to participation in such proposed programs and encouraging such by the various neurological societies, the neurologist must pursue legislation at the federal, state, and local levels addressing these issues. They must educate their colleagues, students, residents, and patients in limiting unessential studies and hospitalizations, becoming allies of third-party payers. They must establish and participate in medical ethics committees for hospital staffs, guiding the appropriate health care and peer review of death and dying for the terminally neurologic patient.

As neurologists we must study the demographics for minority neurology in the United States. Such demographics have yet to be established. While various studies of specific neurologic disorders accumulated in the literature might note the incidence and prevalence of a particular disease in a minority group, usually stated as nonwhite, few indicate specific minority ratios. The changing demographics of the population into the 1990s and the 21st century requires neuro-epidemiologic studies of our shifting black, Hispanic, Asian-American, and Native American populations. One can extrapolate from the Kurtzke[41] data on the neurologic burden of illness and injury in the United States an estimate of individuals with neurologic disorders among the approximated millions of uninsured and underinsured Americans.[36] However, the paucity of minority risk factor data for stroke can be seen in the otherwise comprehensive special report of the World Health Organization task force on stroke and other cerebrovascular disorders published in 1989.[42] Two studies supported by the National Institute of Neurologic Diseases and Stroke are presently addressing the disparity of stroke incidence and mortality between black and white Americans.[43] Studies such as these at Columbia University and the University of Maryland are examples of the need to pursue minority neurologic demographics. A poster presentation on race and incidence of hemorrhagic stroke presented at the stroke meetings in San Francisco is encouraging in this regard.[44]

Finally, the behavior of many office-based neurologists toward Medicaid patients, Medicare assignment, and the many mettlesome problems associated with caring for such patients need to be addressed. Bureaucratic enforced payment fees and burdensome accompanying paperwork are relegating such patients to second-class or lower strata in access to high-level health care. The ever-increasing overhead of the neurologist in office practice limits the entrance of such patients into such quality care assumed by the private-pay patients. Indeed, such rationing of health care inherent in any second-party– and third-party–subsidized delivery system since its inception, is now deeply embedded in various proposals to curtail rising health care costs further challenging the economics and ethics of the office- and hospital-based neurologist. Hence, the neurologist must join the minority community and its leaders in providing incentives to ease such patients in the quality delivery of health care. If various tax and business incentives, long established for businesses and corporations, can be directed toward such access barriers created by Medicaid and Medicare assignments, the neurologist will be aided in behavior modification toward such patients. The skills of the neurologists can be bartered for items of need to exercise such skills just as small businesses are taking such an approach in such recessionary times. The time has come for the community and the health care provider to establish innovative financing strategies to maintain its citizens at the first-class attitudes of both the provider and the recipient.

As Secretary Louis Sullivan, MD, indicated in his keynote address to a satellite meeting of the 1991 International Conference on Stroke, the costs of stroke is a $25 billion health problem and stroke is a discriminating disease disproportionately affecting women and blacks. Secretary Sullivan highlighted access to medical care, contingent on personal responsibility for disease prevention, containment of health care costs, a public health system for the poor, a reexamination of the private insurance system, and providing outcome studies of effectiveness of treatment strategies.[45] In all such areas, the neurologist and neurological societies need participate.

• We evaluated the images of 60 carotid artery bifurcations in 31 patients suspected to have carotid artery disease who underwent invasive carotid angiography and combined two-dimensional, phase-sensitive and a gradient-echo magnetic resonance angiography. The phase scans consisted of seven serial projections that were obtained at 20° intervals (11.0 minutes) around the carotid bifurcation; the gradient-echo (GRASS) scans were composed of 11 axial images (2.4 minutes) acquired through the bifurcation. The two magnetic resonance angiographic techniques yielded complementary pieces of information and were used together to compare magnetic resonance angiography with invasive angiography. Comparison of magnetic resonance and invasive angiograms of the 60 carotid arteries shows that the sensitivity (86%) and specificity (92%) of the magnetic resonance angiographic techniques we used to diagnose clinically significant carotid stenosis approach but do not reach those of invasive angiography.

(*Arch Neurol.* 1991;48:484-489)

Stroke is the third leading cause of mortality in the United States and affects 1.7 million people at any time.[1,2] Up to 15% to 20% of strokes may be related to potentially remediable atherosclerotic changes in carotid arteries.[3] Carotid endarterectomy is generally recommended for symptomatic patients with relevant severe stenosis in their extracranial carotid arteries, at least pending the completion of a number of ongoing trials of this surgical procedure.[4] Platelet antiaggregants (eg, aspirin) are usually employed in patients with less severe carotid artery disease or in those who are at high surgical risk.[5-8]

Patients suspected to have clinically significant carotid atherosclerotic plaques undergo imaging with a variety of techniques. Ultrasound is the most commonly used noninvasive method. Most laboratories employ Duplex scanning, which provides B-mode images, complemented by Doppler flow signals, because the accuracy of B-mode imaging alone decreases as the severity of the stenosis of the carotid artery increases.[9,10] Color-coded Doppler imaging allows simultaneous imaging of blood flow and soft tissue and may prove to be advantageous in the depiction of tortuous vessels, postendarterectomy states, and preocclusive stenosis.[11,12]

Magnetic resonance (MR) angiography is another noninvasive technique that can produce two-dimensional, as well as three-dimensional, images of the carotid arteries. A variety of techniques, which take advantage of either the longitudinal or transverse (phase) magnetization of protons in the field of interest,[13-15] can be utilized to produce images of blood vessels. The purpose of our study was to evaluate the sensitivity and specificity of two MR angiographic techniques compared with invasive angiography in the identification of clinically significant stenosis of the carotid artery near the bifurcation. An older, well-established, phase-sensitive MR angiographic technique was used to produce two-dimensional images similar to those produced by invasive angiography, both to identify stenosis and to localize the carotid bifurcation so that axial gradient-echo images can be obtained through the carotid bifurcation in cross-section. The axial gradient-echo images were acquired to estimate the percentage of stenosis, as they usually disclose more accurate contour information than do the phase images.

PATIENTS AND METHODS

Forty-one patients with suspected carotid artery disease who had undergone invasive carotid angiography (intravenous [IV] digital substraction angiography [DSA], intra-arterial DSA, or conventional invasive angiography) within approximately 24 hours were entered into this open-ended study. Patients were excluded from this study if they were claustrophobic, had a cerebral aneurysm that had been clipped, had a pacemaker, or had recently undergone carotid surgery. After being fully informed about the nature of MR angiography, informed consent was obtained from all the patients who participated in the study.

Of the patients recruited, two were excluded from the study because a scan could not be successfully completed; another two were excluded because some of the images were inadvertently omitted; and a final two were excluded because of mechanical or soft-

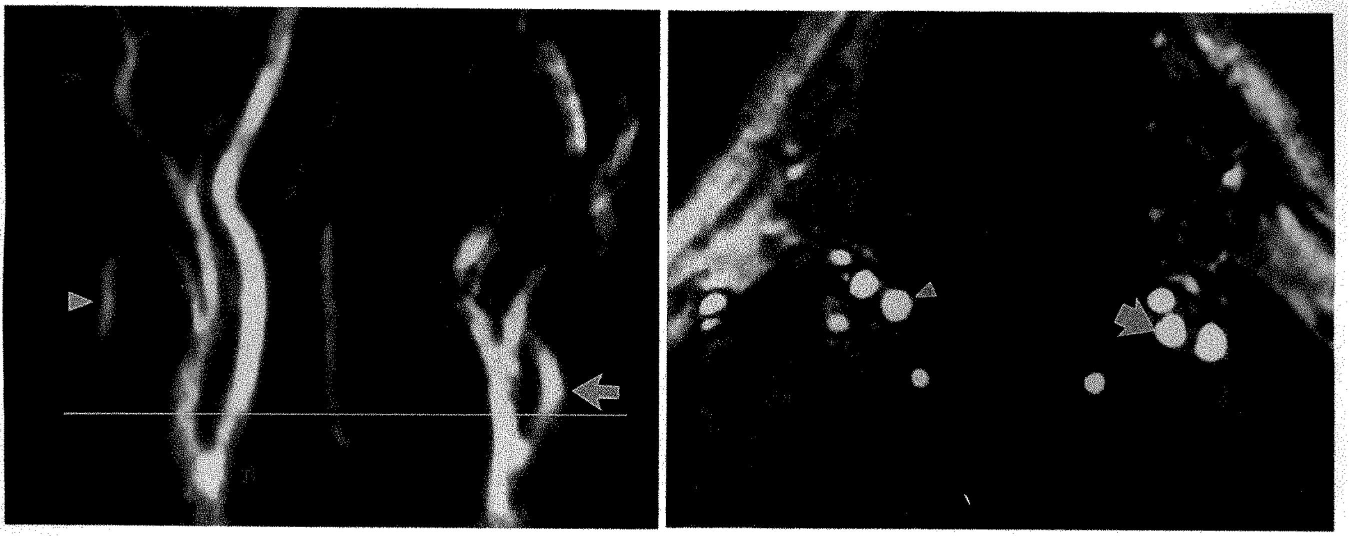

Fig 1.—Images of normal carotid arteries. Left, Magnetic resonance phase-projection angiogram through both carotid artery bifurcations. The right internal carotid artery (ICA) does not overlap the right external carotid artery (ECA) as it does on the left (arrow). The right ICA is medial to the corresponding ECA, while the reverse is true on the left. The right ECA can be differentiated from the ICA because of its branches (arrowhead). Right, Axial gradient-recalled acquisition in the steady state image through the carotid bifurcation (acquired through a plane represented by the horizontal line in Fig 1, left). The right ICA (arrowhead) is posteromedial to the corresponding ECA because of its unusual medial position, while the contralateral left ICA (arrow) is almost directly posterior to the ECA (usual anatomic situation). Both ICAs are slightly larger than the ECAs.

Table 1.—Comparison of Magnetic Resonance (MR) Angiographic and Invasive Angiographic Findings on Degree of Carotid Stenosis

	Invasive Angiogram*							
MR Angiogram	**Normal**	**Minor**	**Moderate**	**Severe**	**Severe/High-Grade†**	**High-Grade**	**Occluded**	**Total**
Normal	7	6	1	0	0	0	0	**14**
Minor	2	7	1	2	0	1	0	**13**
Moderate	2	2	6	0	0	0	0	**10**
Severe	0	1	2	1	0	2	0	**6**
Severe/high-grade†	0	0	0	1	0	0	0	**1**

*Minor indicates 1% to 15%; moderate, 16% to 49%; severe, 50% to 79%; high-grade, 80% to 99%; and occluded, 100%.

†The combined category means that the "gold standard" committee judged the two grades of stenosis to be equally probable.

ware difficulties associated with the scanner.

Both a phase-sensitive, projection angiographic technique and a gradient-echo technique that produces transaxial images were used with a 1.5-T system with linear gradient coils.[15,16] A localizing scan was obtained to ensure that the carotid bifurcations were in the center of the field (2.4 minutes). Seven separate projection images were then obtained at 20° intervals (11.0 minutes; repetition time, 33 msec; echo time, 17 msec; 22 signals averaged; field of view, 16 cm; 256 × 128 matrix).

The projection image that best showed the location of the carotid bifurcation was then used to obtain a sequence of 11 axial images through the carotid bifurcation and proximal internal carotid arteries (Fig 1). The technique of gradient-recalled acquisition in the steady state (GRASS) (2.4 minutes; flip angle, 70°; repetition time 55 milliseconds; echo time, 17 milliseconds; 2 signals averaged; field of view, 16 cm; section thickness, 5 mm; 256 × 128 matrix) was used to obtain the axial images from which the percentage of narrowing was estimated.

Each combined MR angiogram and the corresponding invasive angiogram was interpreted by a panel of physicians, which consisted of a vascular surgeon (K.O.), a neurologist (J.H.), and three neuroradiologists (L.M.K., A.M., J.V.M.). All readings were performed by a minimum of two members of the panel, at least one of whom was a neuroradiologist. The MR images were always reviewed before the invasive angiograms. No history or clinical findings were provided beyond knowledge that the patient was being evaluated for suspected disease of the carotid arteries. The quality of each image was graded to allow separate analysis of those scans that were technically inadequate. The positions of the internal and external carotid arteries were identified, when possible, from the projection images. These images were also used to identify grossly the areas of stenosis. Each carotid artery was evaluated for stenosis relative to the normal segment of the internal carotid artery distal to the stenosis (none; minor, 1% to 15%; moderate, 16% to 49%; severe, 50% to 79%; high-grade, 80% to 99%; or occlusion) based on the axial GRASS images (Fig 1). The axial GRASS images were compared with the phase images, because the former occasionally underestimate the degree of stenosis. A confidence level (seven steps from definite to unlikely) was also assigned to each finding.

Among the 70 carotid arteries examined by the committee, 10 were excluded for one of two reasons: (1) Two carotid arteries were excluded because the invasive angiogram (an IV DSA study) was judged by the "gold standard" committee to be of poor quality. Four other carotid arteries were excluded from the analysis because the MR angiograms were of insufficient quality to be read. (2) Four carotid arteries were excluded because the sum of the committee's confidence in their primary and alternative interpretations of the MR angiograms did not exceed 50%. In these cases, the committee stated that they were having difficulty distinguishing between the internal and external carotid arteries.

The mean age of the 31 patients with carotid arteries analyzed in our study was 69.5 years (range, 48 to 85 years). There were 22 men and nine women. The mean age for the 10 patients enrolled in the study who were later excluded from the analysis was not significantly different (70.2 years); however, these patients were evenly divided between men and women. Ninety percent of the 31 patients underwent intra-arterial invasive angiography, and 10% underwent IV DSA invasive angiography. In all three of the IV DSA studies that were included, the review committee judged the images to be of sufficient quality to permit accurate measurement of carotid stenosis.

Statistical analysis was performed with use of the Statistical Analysis System.[17] Pearson correlation coefficients and Kendall's τ were used as measures of association. Fisher's Exact Test and χ^2 analysis were used for pairwise comparisons of categorical data. Sensitivity and specificity were calculated with standard methods.[18]

RESULTS

Among the 70 carotid bifurcations examined, 60 met our criteria for analysis: the images were of adequate quality and the review committee had reasonable confidence in their readings. All subsequent analyses presented will refer to these 60 carotid arteries.

In 53% of the carotid arteries, the stenosis ratings based on the MR angiograms were an exact match with the results of the corresponding invasive angiograms. Of the remaining pairs, 33% were off by one step or less and 13% by two or more steps (Table 1). Magnetic resonance angiograms overestimated the size of the lumen in 15 of the cases and underestimated it in 13 cases. The correlation between gradings of stenosis based on MR and invasive angiography was .473 for the right side by Kendall's τ correlation coefficient compared with .817 for the left side. These results indicate a highly significant association between the findings of the two tests on both sides.

The clinical significance of the relatively low rate of exact matches (53%) is best evaluated by a comparison of MR angiography with the gold standard—invasive angiography—with use of a 2×2 table to determine the operating characteristics of the MR techniques (Fig 2). Normal findings, as well as minor and moderate stenoses, were regarded as negative (clinically insignificant) results, as the corresponding therapy would probably be medical. In contrast, findings of severe or high-grade stenosis were regarded as positive (clinically significant), as the patients would be potential surgical candidates. For analyses of sensitivity and specificity, occlusion was considered a nonsurgical result. With the use of these definitions, there were 21 carotid arteries with clinically significant stenosis, 38 without clinically significant stenosis, and one occlusion based on the invasive angiograms. With invasive angiographic findings as the gold standard, the sensitivity of MR angiography was 86% (18/21) and its specificity was 92% (36/39). Magnetic resonance angiography was considerably more sensitive in identifying stenosis of the left carotid artery compared with the right.

Right Side

		Invasive Angiography		
		Positive	Negative	
MR Angiography	Positive	8	1	Sensitivity=73%
	Negative	3	18	Specificity=95%

Left Side

		Invasive Angiography		
		Positive	Negative	
MR Angiography	Positive	10	2	Sensitivity=100%
	Negative	0	18	Specificity=90%

Both Sides

		Invasive Angiography		
		Positive	Negative	
MR Angiography	Positive	18	3	Sensitivity=86%
	Negative	3	36	Specificity=92%

Fig 2.—Accuracy of magnetic resonance angiography vs invasive angiography. The right and left carotid arteries are analyzed separately (top and middle) and then together (bottom).

Two of the three false-negative MR readings occurred when the readers did not correctly identify the position of the internal carotid artery. In one case, a large external carotid artery was thought to be the internal carotid artery and thus was read as normal (Fig 3). In the second case, the anatomic variation where the internal carotid lies medial to the external carotid artery was not appreciated and the internal carotid ar-

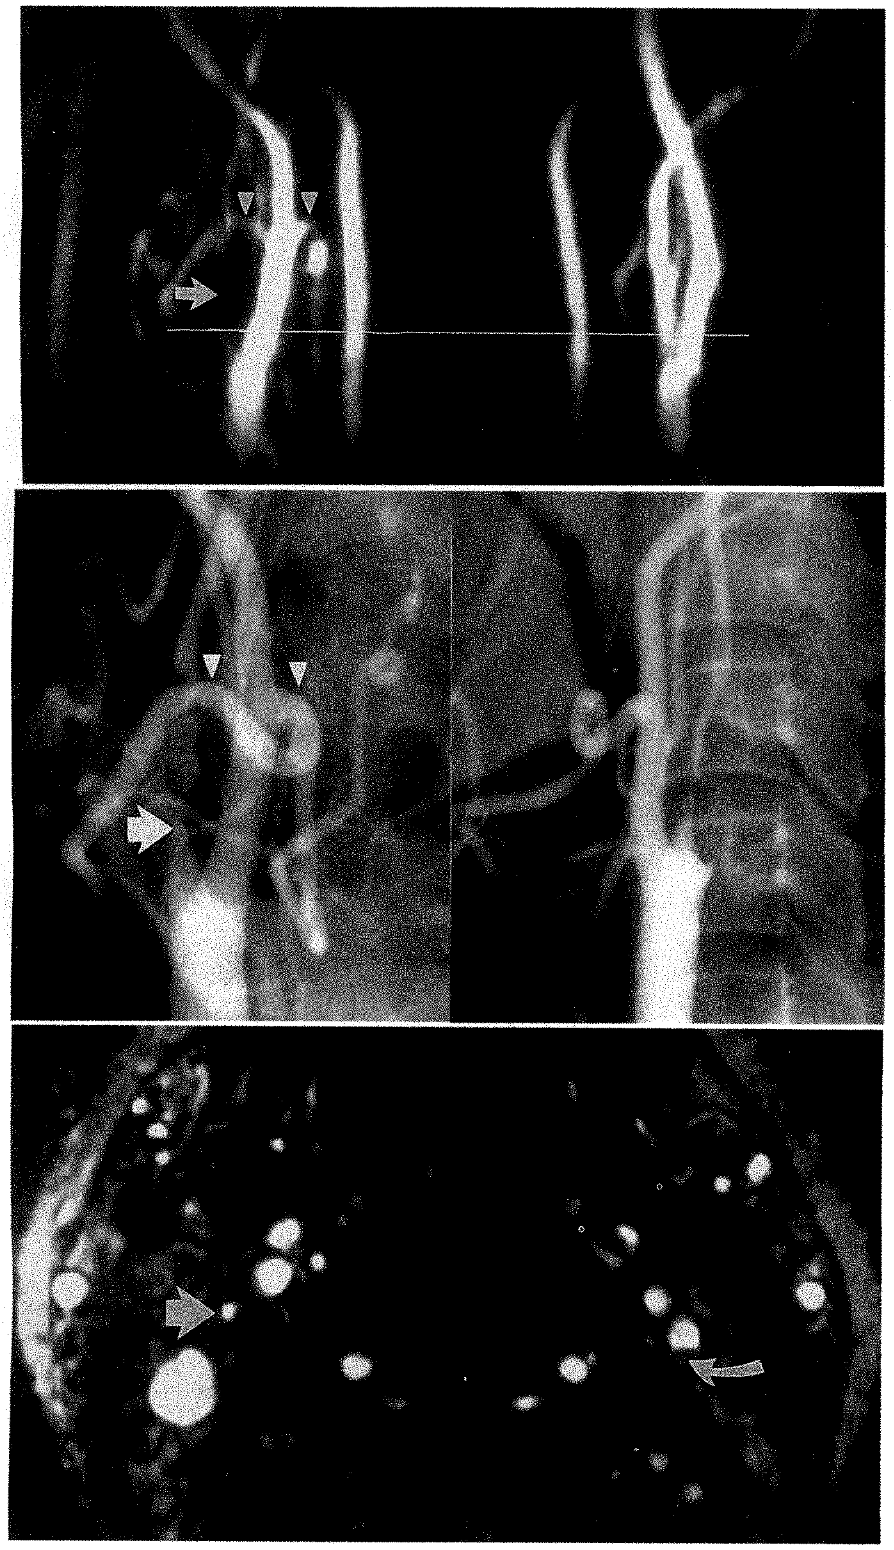

Fig 3.—High-grade stenosis of the right internal carotid artery (ICA). Top, Magnetic resonance phase-projection angiogram shows a prominent artery believed to be a normal right ICA. However, the branches that appear to arise from this vessel (arrowheads) indicate that it is the external carotid artery (ECA). The narrow ICA is lateral to the ECA and shows high-grade stenosis (arrow). Middle left and right, Corresponding anteroposterior (left) and lateral (right) invasive angiograms of the right carotid bifurcation. Note high-grade stenosis of the ICA (arrow). Arrowheads are placed on a branch of the ECA in the left image to correspond to the magnetic resonance phase-projection angiogram (Fig 3, top). Bottom, Axial gradient-recalled acquisition in a steady state images through the neck (acquired through a plane represented by the horizontal line in Fig 3, top). The right ICA shows high-grade stenosis (straight arrow). The left ICA demonstrates minor stenosis due to a small plaque along its posterior wall (curved arrow).

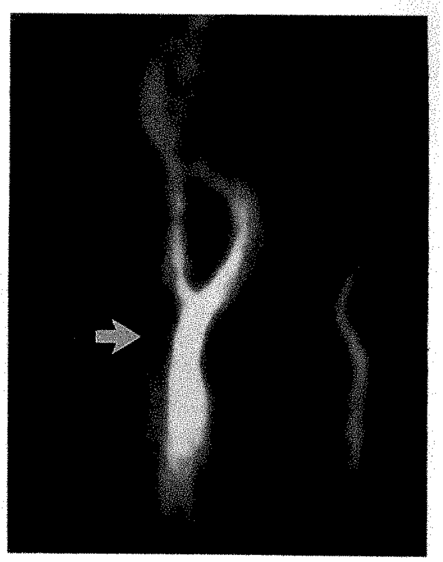

Fig 4.—Medial right internal carotid artery (unusual anatomic position). The lumen of the internal carotid artery was misinterpreted as being normal, because the presence of the superior thyroid artery (arrow) was not appreciated and the lumen size of the external carotid artery was attributed to the internal carotid artery. (Magnetic resonance phase-projection angiogram.)

tery was misjudged to be narrowed (Fig 4). In the third case, the readers underestimated the true stenosis on the MR angiographic images.

The three false-positive readings resulted in cases where the axial GRASS images misrepresented the lumen size of the carotid arteries (Fig 5). In these cases, the lumen appeared to be smaller than it actually was. This distortion might have been suspected by studying the corresponding phase-projection images, which were more similar in appearance to the corresponding invasive angiogram. Four of the six incorrect readings (all three false-negative findings and one false-positive finding) involved the right carotid artery.

The review panel had more confidence in their evaluation of the grade of stenosis when reading the invasive angiograms compared with the MR angiograms. They had a confidence level of 95% or greater (definite or very high) in their readings of 74% of the invasive angiograms vs 28% of the MR angiograms (Table 2).

If the 10 carotid arteries excluded from the analysis had been included, the sensitivity and specificity of MR angiography each would decline slightly. The sensitivity would decline from 86% to 84%; the specificity, from 92% to 87%. The six carotid arteries excluded because of the poor quality of the images included one true-positive, three true-negative, and two false-positive results.

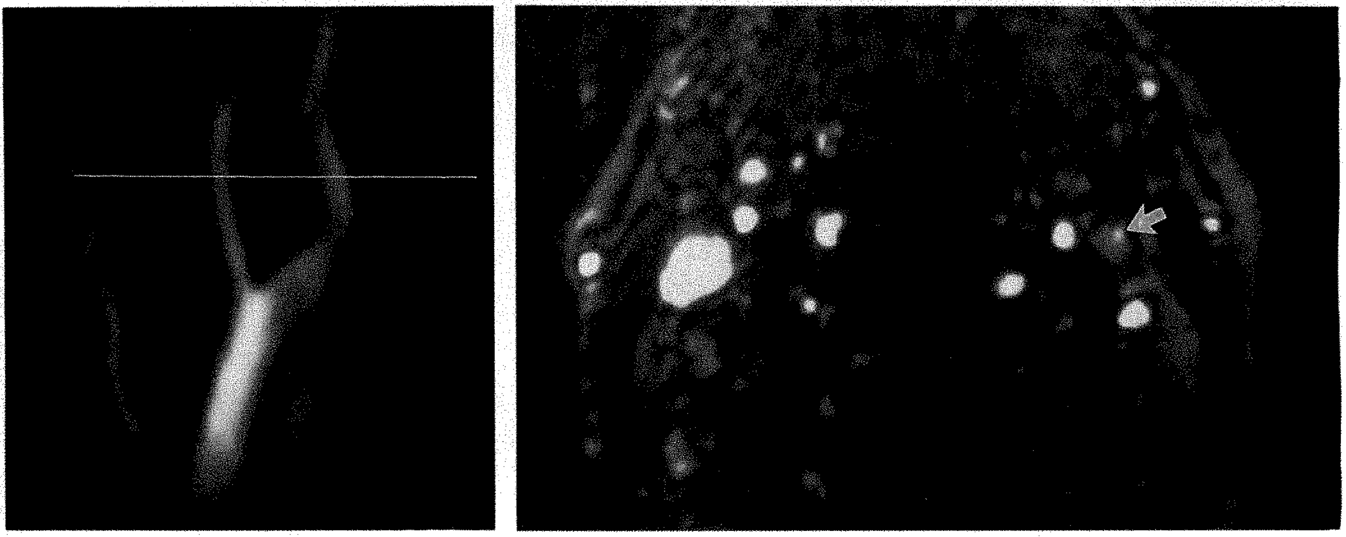

Fig 5.—Minor stenosis of the left internal carotid artery. Left, Phase angiogram appears to be normal. The corresponding invasive angiogram (not shown) disclosed minor stenosis. Right, Axial scan (acquired through a plane represented by the horizontal line in Fig 5, left) shows a small area of high signal intensity (arrow). This was misinterpreted as the residual lumen, so the left internal carotid artery was believed to be severely stenotic. The intermediate signal intensity posteromedial to the high signal intensity, which represents the remainder of the actual lumen, was believed to be a plaque. The right internal carotid artery was judged to have minor stenosis because it was slightly smaller than the corresponding external carotid artery.

Table 2.—Comparison of Degree of Confidence in Readings of Magnetic Resonance (MR) Angiograms vs Invasive Angiograms*

	No. (%)	
Degree of Confidence	MR Angiography	Invasive Angiography
Definite (100%)	...	17 (27)
Very high (95%-99%)	18 (28)	30 (47)
High (76%-94%)	15 (23)	9 (14)
Moderately high (51%-75%)	24 (38)	7 (11)
Moderately low (26%-50%)	6 (9)	1 (2)
Low (6%-25%)	1 (2)	...
Total	**64**	**64**

*This table includes the 60 carotid arteries examined in the analysis and the four carotid arteries excluded because the committee did not have sufficient confidence in their readings. It does not include the six carotid arteries excluded because of poor image quality. Interestingly, the committee's confidence in these six readings did not differ significantly between the invasive and MR angiograms.

The four carotid arteries excluded because of the committee's low confidence in their reading consisted of two true-positive, one false-positive, and one false-negative result.

The 12 remaining carotid arteries excluded were in patients who did not complete the MR imaging procedure as a result of patient or imaging problems. If MR angiography were adopted for clinical practice, however, the four patients (eight carotid arteries) whose imaging procedures were incomplete would have had the missing or inadequate sequences repeated. The two patients (four carotid arteries) who were claustrophobic would have been reassured; if that were inadequate, the patients would have been sedated and the imaging procedure repeated.

COMMENT

Evaluation of an evolving technology is difficult because there are frequently many competing variations, and the newest technique often looks more promising than the older ones. Our study focuses on two well-established MR techniques. Although some might question our reporting on an evaluation of techniques that are no longer on the cutting edge, doing so can be justified for two reasons: (1) It is not clear that just because some of the newer methods produce "prettier" images, they are any more accurate than the older techniques. Until the alternative MR angiographic techniques are compared systematically, it is impossible to conclude which one actually produces the most useful and reliable results. (2) Evaluation of these two methods sets a baseline for the assessment of later techniques. If the results show, as they do in our study, that the operating characteristics of these older techniques come close to those of invasive angiography, they provide additional evidence that MR angiography warrants further, systematic study.

In fact, the results of our study, in which the two older techniques are combined, show that MR angiography can detect clinically significant extracranial carotid artery stenosis without the use of contrast media injection. With invasive angiography as the gold standard, our research shows that MR angiography has good but not perfect sensitivity and specificity.

Our results also indicate that phase (transverse) and longitudinal (gradient-echo) MR angiographic techniques provide complementary pieces of information and thus justify their being evaluated together vs invasive angiography. At least some of the false-positive readings might have been avoided if the gradient-echo images, which underestimated the lumen size, had been compared more carefully with the phase images.

Our study compares the sensitivity and specificity of combining phase-sensitive and gradient-echo MR angiographic techniques with conventional invasive angiography in the identification of clinically significant stenosis of the carotid artery bifurcation. Previously, we had determined that MR angiography does not need to be perfectly sensitive or specific, because a small loss of accuracy would be offset by the lower risk of MR angiography. We estimated, with the use of decision analysis, that carotid MR angiograms can be either 5% less sensitive or 15% less specific than invasive angiograms and still yield the same benefit.[19] Based on these preliminary results, the 86% sensitivity and 92% specificity of MR angiography approach these criteria.

We used invasive angiography as the gold standard for this analysis; it is possible that some apparent MR angiography errors were actually the result of invasive angiography errors. However, analysis with use of only the best MR and invasive angiograms yielded essentially the same results. Similarly, inclusion of the three cases (six carotid arteries) in which IV DSA was used did not lower the operating characteristics of MR angiography, as there were three true-positive and three true-negative results.

Four of the six incorrect readings were of the right carotid artery. Two of the four (two false-negative results) can be attributed to the anatomic variation where the internal carotid artery lies medial to the external carotid artery; this occurs in 17.6% of right carotid arteries and only 5.2% of left carotid arteries.[20] Therefore, it is not surprising that MR angiograms of the right carotid artery were misread more often. However, new three-dimensional, time-of-flight MR angiographic techniques should help overcome this problem by providing a more detailed picture of the carotid bifurcation, whereby the branches of the external carotid artery can be routinely identified.[21-23]

Although our results are promising, it may be difficult for individuals who are inexperienced in the interpretation of MR angiograms to duplicate them. The panel of physicians had been reading normal and abnormal MR angiograms for about 1 year before these images were read for study purposes, and they had become acquainted with many of the pitfalls of MR angiogram interpretation. Furthermore, MR angiograms may be more difficult to read than traditional invasive angiograms, as reflected by the approximately 15 to 20 minutes necessary to read a combined MR angiogram vs roughly 5 minutes for an invasive angiogram.

Several of our findings are consistent with MR angiography being a new technology. In this initial work, the MR angiographic images were more often of lower quality than the invasive angiograms, which could have affected the length of time it took for the committee to read them. Readers' confidence in their gradings of stenosis was consistently lower with MR angiography than with invasive angiography. Both of these differences should decrease as the technology improves and as the readers become even more familiar with it. Consequently, we anticipate that as the field evolves, both the sensitivity and specificity of MR angiography should improve. In fact, some of the techniques presently available elsewhere, individually or in concert, may yield more accurate results than those reported in this study.[22,23] However, past methodologic evaluations of MR studies have shown that strict adherence to sound technologic assessment methods has been the exception rather than the rule.[24,25] Reports of improved results with newer MR techniques should be examined carefully.

This investigation was supported in part by grant NS24724 from the National Institutes of Health, Bethesda, Md.

Delayed Visual Loss due to Trauma of the Internal Carotid Artery

Joel M. Weinstein, MD; Daniel A. Rufenacht, MD; Curtis R. Partington, MD, PhD; Virgil B. Graves, MD; Charles M. Strother, MD;
Richard E. Appen, MD; Daniel M. Jacobson, MD; Terry A. Cox, MD; Mark L. Moster, MD

• The group of six patients in this study experienced delayed visual loss following head trauma. Visual loss occurred from 1 day to 13 years after the initial injury. All patients suffered indirect trauma to the internal carotid artery resulting in formation of either an aneurysm or pseudoaneurysm or a carotid-cavernous fistula. Review of the radiologic and clinical findings was performed in six patients. The diagnosis was established by computed tomography, magnetic resonance imaging, and angiography. All patients had follow-up clinical evaluation and imaging studies. Treatment by neurosurgical or interventional neuroradiologic procedures resulted in significant visual improvement in five patients. Different pathophysiologic mechanisms could be correlated with the delayed visual loss produced by the two types of lesions. The pathologic changes associated with the aneurysms/pseudoaneurysms included direct compression of optic nerves and/or chiasm and intracranial hematoma. A carotid-cavernous fistula caused delayed visual loss by either hematoma at the orbital apex or compression of the chiasm and/or optic nerves by saccular dilatation of the cavernous sinus. The delayed onset of decreased vision following head trauma should alert the physician to the possibility of a traumatic aneurysm/pseudoaneurysm or a carotid-cavernous fistula. Different neuro-ophthalmologic symptoms can usually be correlated with the pathologic changes demonstrated by neuroimaging procedures.

(*Arch Neurol.* 1991;48:490-497)

Optic nerve damage is a well-recognized complication of closed head trauma.[1-3] In the majority of patients in whom vision can be assessed, visual loss is immediate and nonprogressive. In a significant minority of patients, visual deterioration occurs after an initial stable interval of 12 to 72 hours, at times without an immediate posttraumatic visual deficit. We have observed six patients in whom visual loss occurred weeks to years after an episode of head trauma (Table). The clinical histories of three patients are given in detail. All patients sustained damage to the internal carotid artery. Two different pathophysiologic mechanisms for visual loss were identified. In two patients, visual loss resulted from compressive optic neuropathy due to a carotid-cavernous fistula. In four patients, a traumatic aneurysm or pseudoaneurysm of the carotid artery caused optic nerve compression. In all of the patients with aneurysms or pseudoaneurysms, and in one patient with carotid-cavernous fistula, intervention resulted in prompt restoration of vision to near normal.

REPORT OF CASES

CASE 1.—**Clinical History and Examination.**—A 21-year-old man was in good health until July 1988 when he sustained bilateral basilar skull fractures in an automobile accident. He was unconscious for 3 to 4 hours and awoke with complete loss of vision in the left eye. Vision in the right eye was 20/20. A left third nerve palsy was present; there were also palsies of nerves VII and and V1-3. Intractable keratopathy necessitated a complete left tarsorrhaphy in August 1988. He had had no visual complaints and was able to read small newsprint without difficulty until September 1988, when he noticed progressive visual loss in the right eye. His visual acuity at that time was 20/50 in the right eye, and there was no light perception in the left eye. About 2 weeks after the onset of visual loss, he noted proptosis and redness of the right eye as well as a bruit in the right ear. A right periorbital headache was present. By mid-October 1988, his vision in the right eye had dropped to 20/400.

On January 25, 1989, the patient's visual acuity was 20/400 eccentrically in the right eye and no light perception in the left eye. He correctly identified only six of 14 color plates. The right pupil reacted sluggishly and the left pupil, which could be seen only in its medial aspect at the edge of the tarsorrhaphy, appeared to be fixed and dilated. The visual field of the right eye showed central and inferior arcuate loss (Fig 1). Mild palsies were present in the following cranial nerves: right VI, right IV, left V1-3, and left VII, with aberrant regeneration of left VII. Motility of the left eye could not be fully evaluated because of the tarsorrhaphy, but there was mildly decreased adduction. The right optic disc and retina were normal, except for mild dilation and tortuosity of the veins. The left optic disc was pale with a slightly decreased caliber of the retinal vessels. A high-pitched, low-intensity bruit was heard best over the right orbit, retromastoid area, and posterior occiput. The exophthalmometry reading was 22 mm in the right eye, and it was not obtainable in the left eye because of the tarsorrhaphy. The palpebral and bulbar conjunctiva and the episclera contained typical "corkscrew" vessels. Intraocular pressure was24 mm Hg in the right eye,

Clinical Histories After Head Trauma*

Patient No./ Age, y/Sex	Pathologic Findings	Time From Injury to Visual Loss	Visual Function: At Time of Trauma	Visual Function: At Time of Visual Loss	Visual Function: After Recovery	Comment
1/21/M	R CC fistula	10 wk	OD, 20/20; OS, NLP	OD, 20/400, central and inferior arcuate; OS, NLP	OD, 20/25, small temporal field defect; OS, NLP	Treatment by intra-arterial balloons
2/18/M	R CC fistula; R ICA aneurysm originating in horizontal intracavernous segment	10 d	OD, 20/200; OS, 20/20	OD, FC 90 cm (3 ft); OS, 20/20	OD, FC 90 cm (3 ft); OS, 20/20 due to CC fistula; no treatment	Orbital apex hemorrhage due to CC fistula
3/26/F	L CC fistula	12 y	OD, 20/20, NL fields; OS, 20/100, nasal island remaining	OD, 20/20, paracentral scotoma; OS, unchanged	OD, 20/20, NL field; OS, unchanged	Treatment by intra-arterial balloons
4/21/F	Intracavernous aneurysm of R ICA; large subfrontal extradural hematoma	8 mo	OD, 20/20; OS, 20/20	OD, 20/30, large paracentral scotoma; OS, 20/20	OD, 20/20, NL field; OS, 20/20, NL field	Epistaxis; treatment: by intra-arterial balloons
5/28/M	Supraclinoid aneurysm of R ICA	8 wk	OD, 20/20, NL field; OS, 20/20, NL field	OD, 20/400, temporal hemianopia; OS, 20/20, NL field	OD, 20/20, NL field; OS, 20/20, NL field	Treatment: intracranial ligation of aneurysm
6/34/M	Intracavernous aneurysm in R ICA	17 y	OD, NLP; OS, NL vision	OD, NLP; OS, 20/50, inferior NFB	OD, NLP; OS, 20/20, field defect improved	Unsuccessful balloon embolization; ICA trapping via intracranial and cervical ligation

*CC indicates carotid cavernous; FC, finger counting; ICA, internal carotid artery; NFB, nerve fiber bundle; NL, normal; and NLP, no light perception.

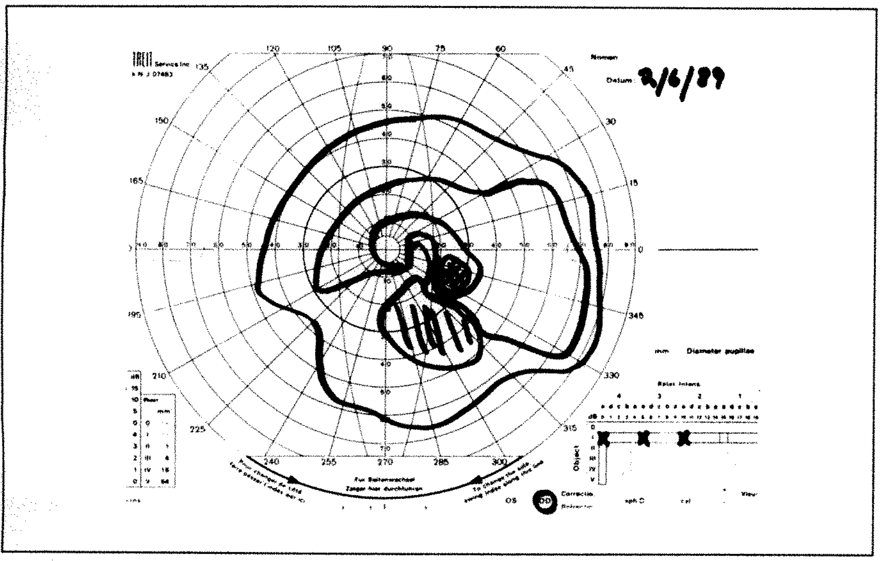

Fig 1.—Visual fields in the right eye of patient 1 showing central and inferior arcuate loss. Vision in the left eye was no light perception.

but it could not be assessed in the left eye because of the tarsorrhaphy. The remainder of the ophthalmologic and general neurologic examination showed normal findings.

Radiologic Studies.—The radiographic examination carried out 6 months after the trauma revealed a large right carotid-cavernous fistula with massive expansion of the cavernous sinus and compression of the suprasellar structures. A computed tomographic (CT) scan with axial and coronal sections confirmed the gross enlargement of the cavernous sinus, predominantly on the right side. The rounded mass entirely filled the suprasellar cistern and extended up and slightly to the left of the midline. There was retrosellar extension indicating dilated inferior petrosal sinuses on both sides. The superior ophthalmic veins were grossly enlarged, on the right more than on the left. Magnetic resonance imaging (MRI) (Fig 2, left) better defined the extent of the dilated cavernous sinus in multiplanar images. The rounded mass appeared to be a thin-walled, aneurysmlike dilation of the cavernous sinus. There was clear evidence of mass effect on the optic pathways with the chiasm draped anteriorly above this varix.

Cerebral arteriography (Fig 2, right) demonstrated that all of the flow from the right internal carotid artery was directed into a carotid-cavernous fistula located at the C3 portion of the siphon. There was immediate filling of the previously described pouchlike extension of the cavernous sinus with immediate opacification of the venous system. The drainage included both inferior petrosal sinuses and, to a somewhat lesser extent, the superior ophthalmic veins, greater on the right than on the left. There was also evidence of retrograde drainage into the cerebral veins. The right external carotid injection demonstrated retrograde flow of the ophthalmic artery, partially feeding the carotid-cavernous fistula. There was collateral flow to the fistula from the left internal carotid artery and vertebrobasilar system via the anterior communicating artery and the posterior communicating artery, respectively. The right posterior communicating artery was markedly bowed upward by the dilated cavernous sinus.

Because the visual loss was felt to be caused by compression of the optic pathways by the pouchlike extension of the cavernous sinus, it was decided not to place detachable balloons within the large fistula itself to avoid substituting the mass effect of balloons for that of the dilated cavernous sinus. For this reason, the fistula was trapped by carotid occlusion with endovascular balloons, which were placed in the internal carotid artery above and below the point of fistulization. There was immediate return of the right posterior communicating artery to its normal position, indicating immediate collapse of the varix.

Follow-up angiography (not shown) and MRI (Fig 3) 4 days after treatment demonstrated persistent collapse of the previously

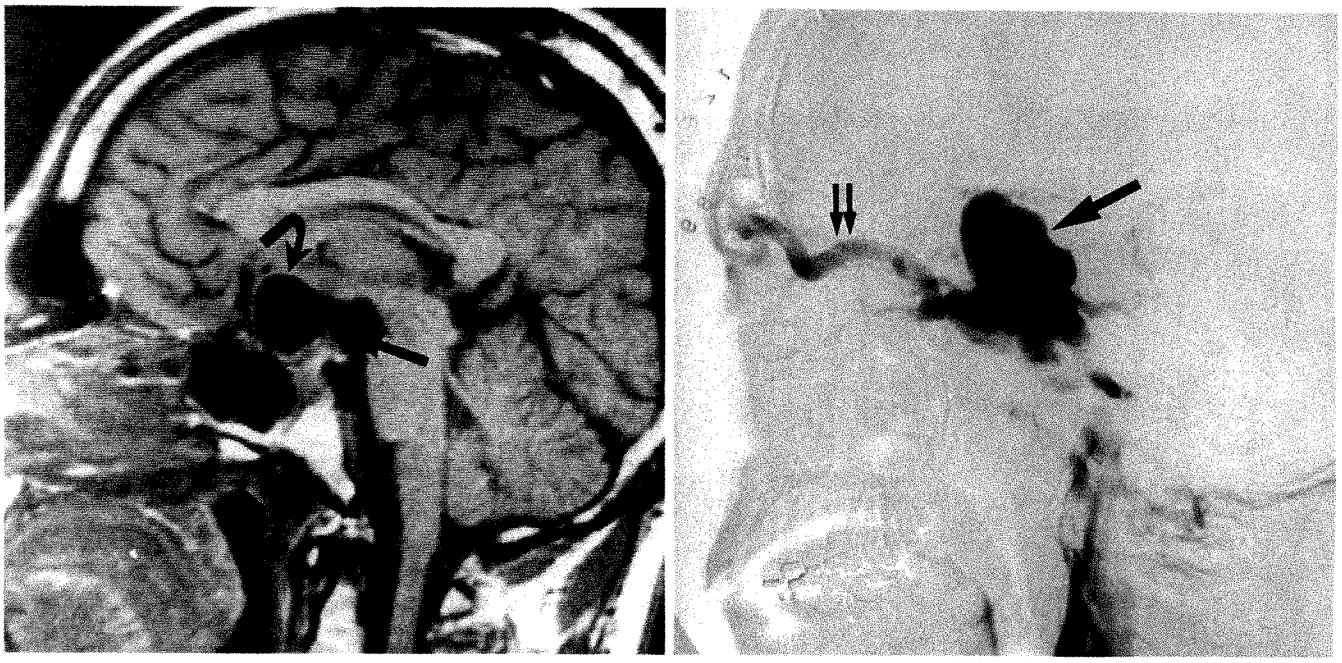

Fig 2.—Sagittal (left) T_1-weighted magnetic resonance image (Signa, General Electric, Schenectady, NY) (1.5 T; TR, 600 milliseconds; TE, 20 milliseconds) and right internal carotid arteriogram (right) of patient 1 at time of presentation. The massively dilated cavernous sinus (single arrows) displaces the optic chiasm (curved arrow) and drains into a dilated right superior ophthalmic vein (double arrows).

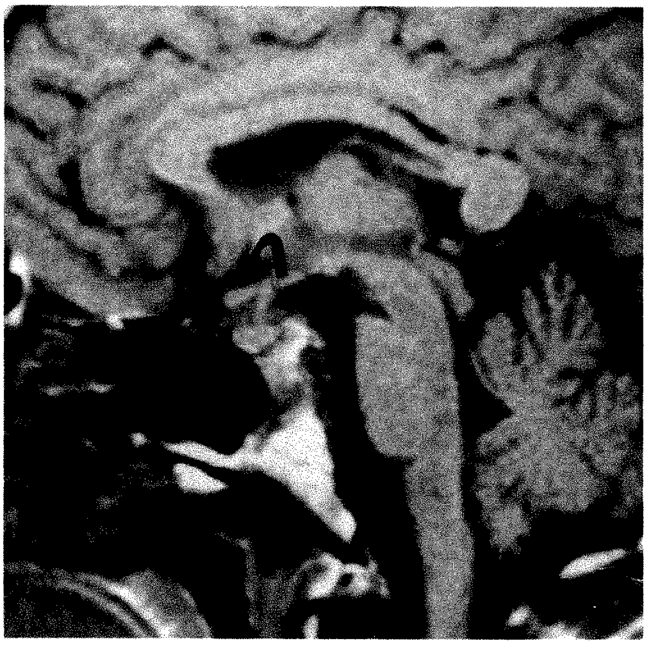

Fig 3.—Sagittal T_1-weighted magnetic resonance image (Signa, General Electric, Schenectady, NY) (1.5 T; TR, 600 milliseconds; TE, 20 milliseconds) of patient 1 four days after right internal carotid occlusion and trapping of fistula. Compare with Fig 2, right. Cavernous sinus has decompressed with return of optic chiasm (curved arrow) to normal position.

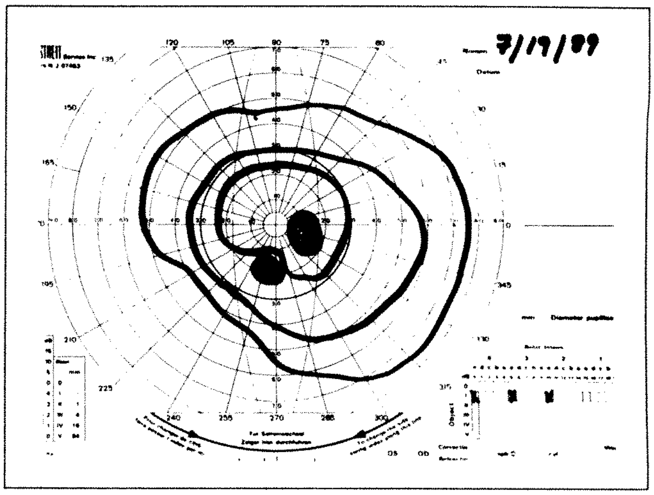

Fig 4.—Visual field in the right eye of patient 1, 5 months after treatment.

dilated cavernous sinus and normalization in the appearance of the intracranial optic pathways.

Clinical Follow-up.—Eighteen hours after angiography and right internal carotid artery occlusion, the patient's visual acuity was 20/25 in the right eye, and there was no light perception in the left eye. The proptosis had diminished, and the episcleral and conjunctival vasculature on the right side was less engorged. The visual fields were improved, though the ocular motility and the appearance of the fundi were unchanged. The bruit was not audible. Results of the reexamination 6 weeks later were unchanged except for a decrease in the caliber of the retinal veins and improvement of visual acuity in the right eye to 20/20. Only a small temporal field defect remained 5 months after the procedure (Fig 4).

CASE 2.—**Clinical History and Examination.**—An 18-year-old man was involved in a motor-vehicle accident on July 5, 1988, and sustained facial and basilar skull fractures, intraventricular hemorrhage, and a right-sided pneumothorax. He was unconscious briefly, and remained in the intensive care unit for 6 days, with gradual improvement in his mental status. When first seen by an ophthalmologist 4 hours after his injury, he was unable to cooperate for tests of visual acuity; pupils were recorded as 4 mm OU in room light with normal light reaction and no afferent defect. Ocular motility was not tested, and results of the fundus examination were recorded as normal. When he was alert

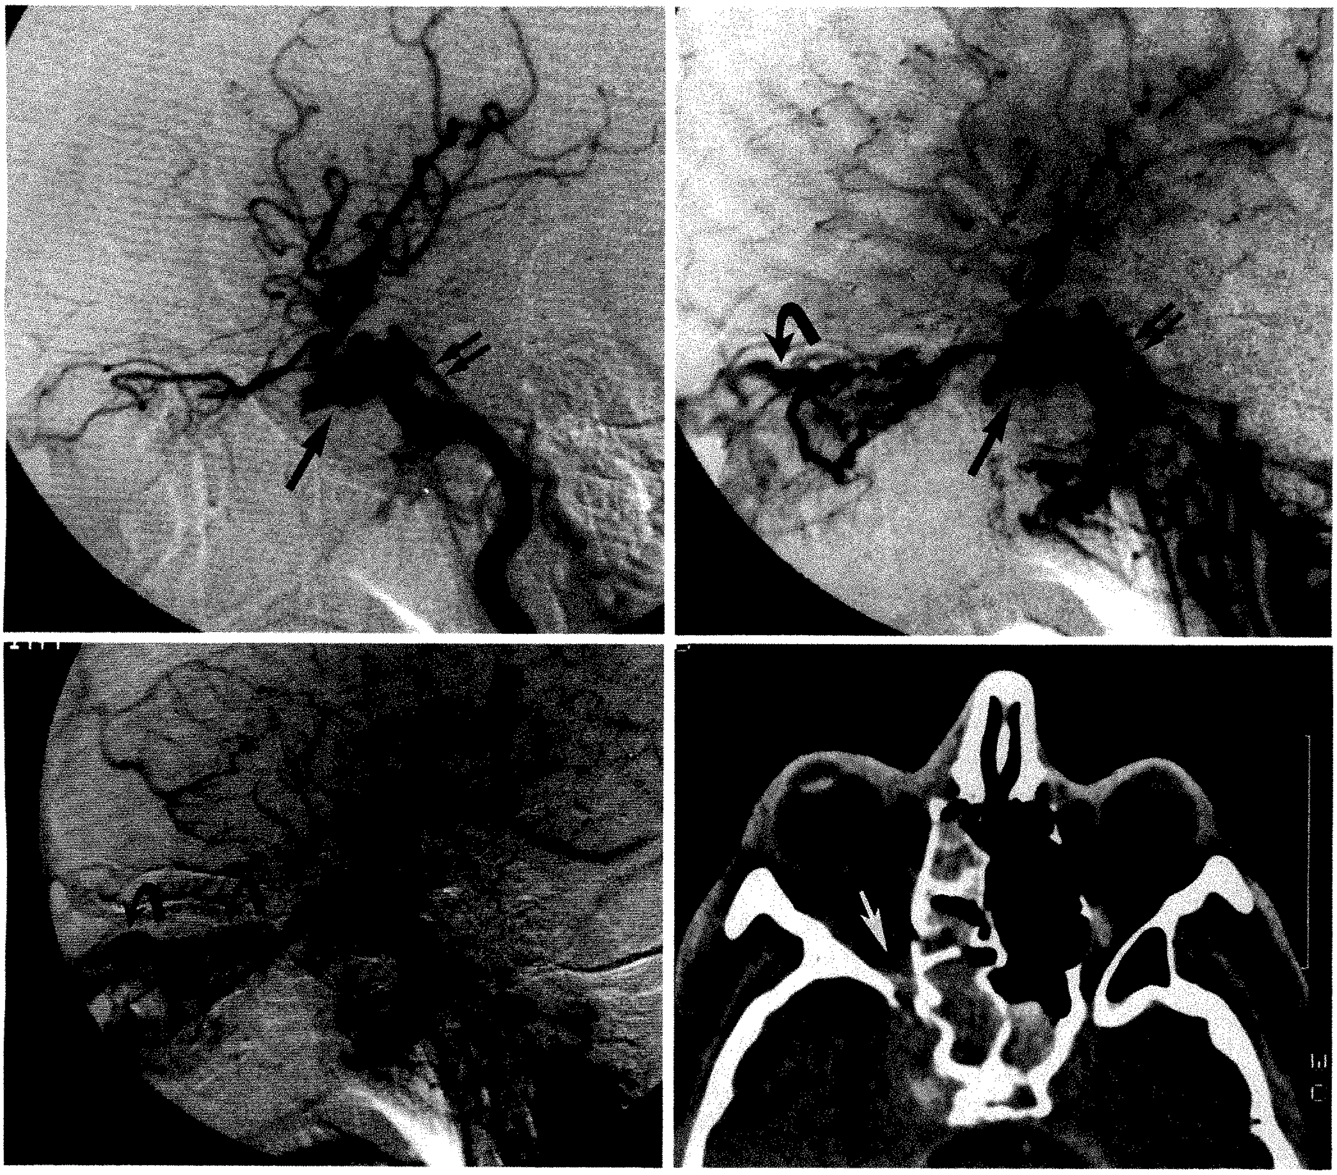

Fig 5.—Early arterial (top left), middle phase (top right), and venous (bottom left) phases from a right internal carotid arteriogram and axial computed tomographic scan through the orbits (bottom right) of patient 2. Note early filling of cavernous (single arrows) and petrosal sinuses (double arrows) and abnormal filling of superior ophthalmic vein (curved arrows), which becomes progressively more distended in bottom left. The superior ophthalmic vein does not drain into the cavernous sinus but appears obstructed at the orbital apex (short arrow). The image shown at the bottom right demonstrates an abnormal soft-tissue density mass in the orbital apex (single arrow), an abnormally enlarged cavernous sinus (curved arrows), and fluid in the ethmoid air cells and sphenoid sinuses.

enough to respond appropriately on the third hospital day, his vision was recorded as 20/200 OD and 20/20 OS. A complete palsy of the right third nerve as well as partial palsies of the right sixth, right seventh, and left sixth nerves were present. Three days later, his visual acuity was recorded as 20/400 OD and 20/20 OS. By the 10th day after the accident, his vision had declined to counting fingers at 120 cm (4 ft) in the right eye, but this was attributed to corneal exposure and use of topical ointments. Eleven days after the accident, vision in the patient's right eye was recorded as counting fingers at 90 cm (3 ft), and there was mild swelling of the right optic disc. Fourteen days after the injury, the visual acuity in the right eye had declined to hand motions, and moderate conjunctival chemosis was present. The patient now noted a bruit in his right ear. Sixteen days after his injury, the patient experienced a sudden bout of epistaxis with approximately 750 mL of blood from the right nostril. Visual acuity in the right eye had declined to light perception. Twenty-four hours after his epistaxis, the patient was transferred to the University of Wisconsin Hospital, Madison.

On examination, visual acuity was bare light perception in the right eye and 20/20 in the left eye. The right pupil was 7 mm and nonreactive, while the left pupil was 3 mm and briskly reactive. A reverse afferent defect (4+) was present on the right side. Confrontation visual fields were full in the left eye, but this test could not be performed in the right eye. Ocular motility of the left eye was normal, but the right eye was immobile except for 2 mm of abduction. An external examination revealed diffuse injection and mild chemosis of the right conjunctiva with no corkscrew vessels. Exophthalmometry readings were 22 OD and 21 OS. Slit-lamp examination findings were unremarkable, and determination of intraocular pressure by Schiotz tonometry was 0 mm Hg OD and 14.6 mm Hg OS. The right optic disc was moderately swollen without spontaneous venous pulsations. The macula, vessels, and periphery were normal. The left optic disc was flat with normal vascularity. The left macula, vessels, and periphery were normal. No per-

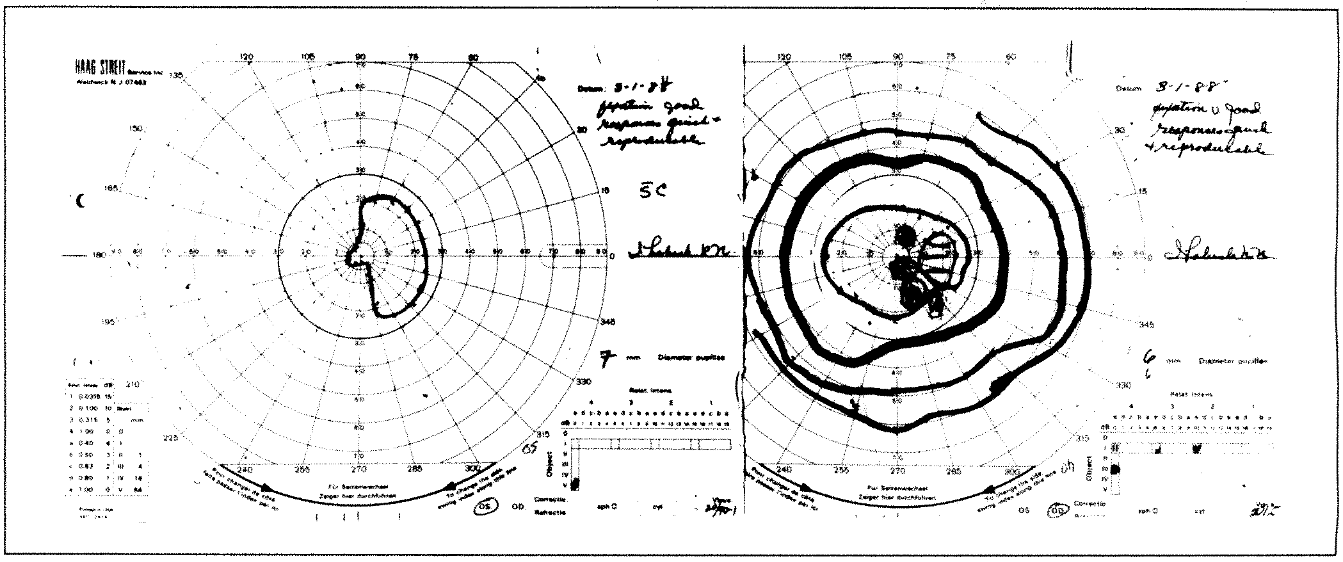

Fig 6.—Visual fields in patient 3 at the time of presentation, 12 years after her injury.

iorbital or cranial bruits were audible, despite the patient's subjective bruit.

Radiologic Studies.—A CT scan performed on July 5, 1988, demonstrated a fracture through the greater wing of the sphenoid bone, extending into the right orbit. There were no extraconal or intraconal orbital lesions. The superior ophthalmic veins were of normal size. There were comminuted fractures of the right ethmoid sinus, and fluid was found in all of the sinuses. A longitudinal fracture extended through the right petrous bone. Pneumocephalus was present, and there was blood in the basilar cisterns. On July 7, 1988, a CT scan showed mild dilation of the right superior ophthalmic vein, but the orbital apex was not imaged in its full vertical extent (middle and superior portions only). An MRI taken on July 13, 1988, demonstrated further enlargement of the right superior ophthalmic vein, extending to the superior orbital fissure, with slight dilation of the right cavernous sinus. However, these changes were not appreciated prior to the onset of epistaxis on July 21, 1988. Carotid arteriography performed on July 22, 1988 (Fig 5), 20 hours after the episode of epistaxis, demonstrated a carotid-cavernous fistula draining primarily toward the right inferior petrosal sinus and partially to the inferior ophthalmic vein through a small communicating vein about the size of the ophthalmic artery. There was delayed filling, via collateral blood vessels, of the right superior ophthalmic vein, which abruptly tapered at the orbital apex and did not empty into the cavernous sinus. These changes were interpreted as consistent with extrinsic compression of the superior ophthalmic vein at the orbital apex, possibly by a hematoma. The mass effect at the orbital apex was confirmed by a CT scan performed on the same day (Fig 5, bottom right).

Clinical Follow-up.—The patient was transferred to the University of Wisconsin Hospital for treatment of the carotid-cavernous fistula. Angiography on arrival demonstrated spontaneous thrombosis of the fistula with only a tiny (<4-mm diameter) pseudoaneurysm remaining. No further treatment was undertaken, and follow-up arteriography performed 12 months later demonstrated a significant decrease in the size of the pseudoaneurysm. Vision has remained 20/20 in the left eye and bare light perception in the right eye.

CASE 3.—**Clinical History and Examination.**—A 26-year-old woman noted blurred vision in her right eye over several weeks. Twelve years previously, she had sustained a basilar skull fracture and traumatic left optic neuropathy in an automobile accident. Vision in the right eye was normal after the accident, and the patient had no further visual complaints until January 1988 when she noted the gradual onset of blurred vision in her right eye and a mild bifrontal headache. She denied symptoms of neurologic dysfunction.

In January 1988, the patient's visual acuity was 20/20 OD and 20/100 OS. Visual fields showed a small nasal island of vision remaining in the left eye and a temporal paracentral scotoma in the right eye (Fig 6). Pupils were equal in size but a left afferent defect (4+) was present. The anterior segment was normal in both eyes, and the intraocular pressures were 12 mm OD and 15 mm OS. There was mild temporal pallor of the right optic disc with normal macula, vessels, and periphery. The left optic disc was extremely pale with normal macula, vessels, and periphery. The remainder of the neurologic examination and general physical examination showed normal findings.

Radiologic Studies.—The radiologic examination revealed a giant, partially thrombosed aneurysm of the left internal carotid artery extending into the suprasellar cistern and compressing the chiasm and intracranial optic nerves. A CT scan performed on January 19, 1988 (not shown), demonstrated a mass in the sellar region encroaching on the left sphenoid sinus. There were secondary bony changes with mottling of the lateral wall of the left sphenoid sinus and elevation of the left anterior clinoid process.

The MRI (Fig 7, left and center) demonstrated the size of the lumen of this partially thrombosed aneurysm to be 1.2 × 1.6 × 2.5 cm. The outer dimensions of the thickened mass proved to be 2.5 × 2.5 × 3.6 cm. The aneurysm extended inferiorly into the sphenoid sinus and superiorly into the suprasellar cistern with elevation of the chiasm and marked deviation of the left optic nerve along the superior lateral aspect of the mass. The thrombosed portions of the aneurysm wall showed a concentric lamination.

Cerebral arteriography demonstrated lateral displacement of the left carotid siphon, with the neck of the aneurysm in the anterior medial portion of the intracavernous segment. Good collateral blood flow to the left cerebral hemisphere was demonstrated. After tolerance of temporary occlusion of the left internal carotid artery, permanent balloon occlusion of the left internal carotid artery was carried out.

Follow-up MRI (not shown) initially demonstrated thrombosis of the aneurysm and the internal carotid artery proximal to the origin of the ophthalmic artery. Subsequent MRIs demonstrated loss of the previously apparent lamination within the wall of the aneurysm with later gradual decrease in size of the mass and marked shrinkage of the thrombosed aneurysm 1.5 years after the endovascular treatment (Fig 8). There was partial restoration of the chiasm toward its normal position.

Clinical Follow-up.—The patient's visual acuity and visual fields were unchanged after undergoing the procedure. Over the ensuing 12 months, the field defect in the right eye gradually and completely resolved. The visual acuity and visual field in the left eye did not change.

COMMENT

Injury to the internal carotid artery may result in partial or complete rupture of any of the vascular layers with resulting dissection,[4] carotid cavernous

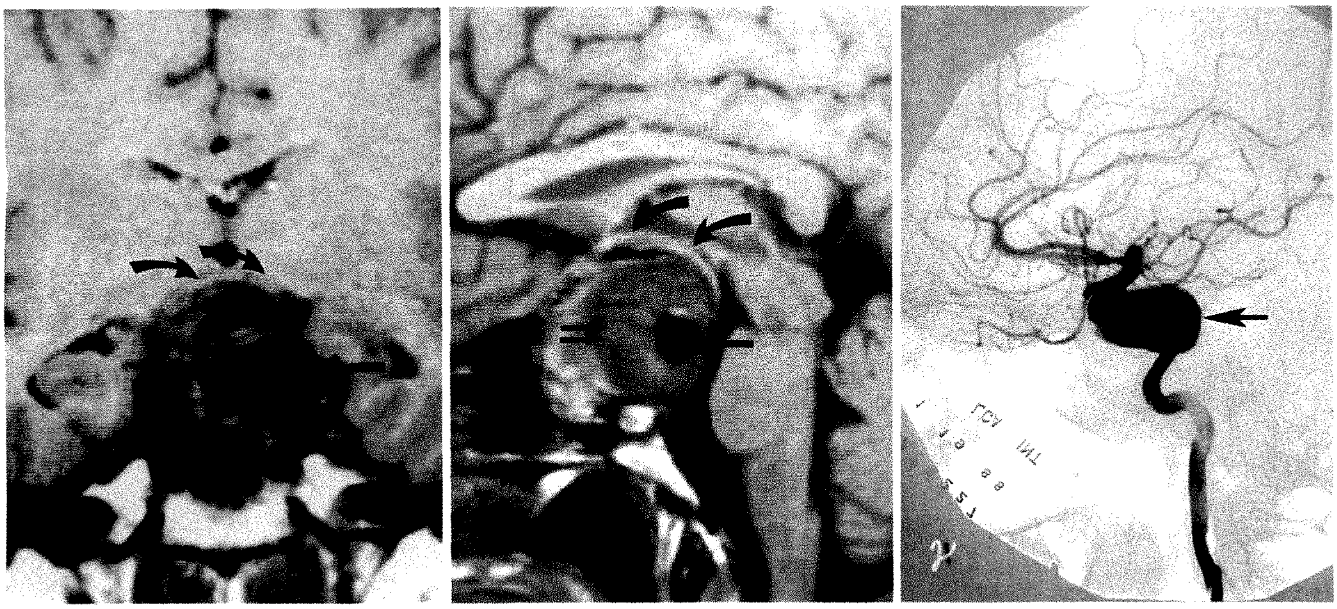

Fig 7.—Coronal (left) and sagittal (center) T_1-weighted magnetic resonance image (MRI) (Signa, General Electric, Schenectady, NY) (1.5 T; TR, 600 milliseconds; TE, 20 milliseconds) and lateral view of a right internal carotid arteriogram (right) of patient 3 at time of presentation. The MRI shows displacement and compression of the optic chiasm (curved arrows) by an aneurysm with a central lumen (single arrows) with mural thrombus (double arrows). Arteriography confirms presence of aneurysm.

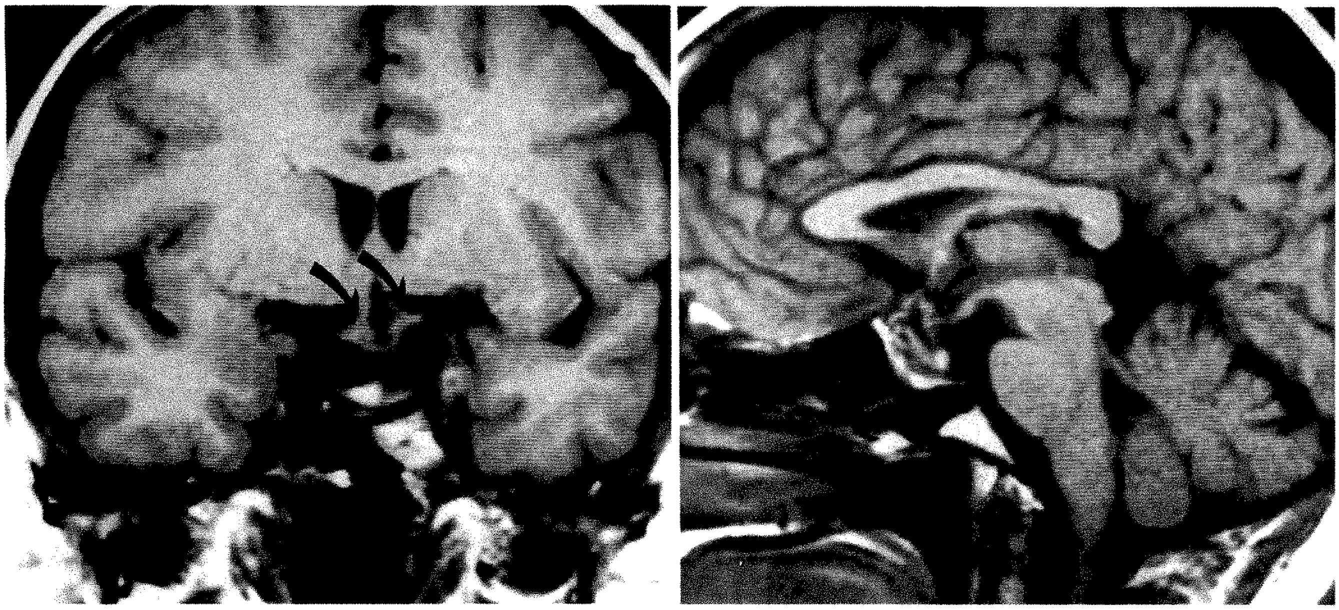

Fig 8.—Coronal (left) and sagittal (right) T_1-weighted magnetic resonance image (Signa, General Electric, Schenectady, NY) (1.5 T; TR,600 milliseconds; TE, 20 milliseconds) of patient three, 1.5 years after treatment. Note the striking resolution of the mass (compare with Figs 7, left and center) with return of the optic chiasm (curved arrows) to a more normal position.

fistula,[5-7] or formation of a false or pseudoaneurysm.[8-11] Distinction between a true aneurysm, false aneurysm, and a pseudoaneurysm is usually not possible without pathologic examination. A traumatic, rather than spontaneous, origin in patients with aneurysms of the carotid siphon region is highly likely when basilar fractures involve the sphenoid and sellar areas (Fig 9) or when a hemorrhage is observed in the sphenoid or posterior ethmoid sinuses or intracranially in the parasellar area. In all of the patients in this study, carotid injury resulted in delayed visual loss due to optic nerve compression. In two patients, visual loss was due to complications arising from a direct carotid-cavernous fistula. Direct compression by the greatly expanded cavernous sinus caused gradual visual loss in patient 1, and hemorrhage at the orbital apex apparently caused rapid visual loss in patient 2. In patients 3 through 6, optic nerve compression resulted from an aneurysm or pseudoaneurysm of the carotid artery. The site of aneurysm formation was the distal intracavernous segment in patients 3 through 5 and the supraclinoid segment in patient 6. In patient 2, an acute visual deficit resulted from periarterial hemorrhage associated with epistaxis. By contrast, visual impairment was not apparent for weeks to years after trauma in the other three patients with aneurysms, apparently because of gradual enlargement of the mass. Recognition of the cause of optic nerve compression led to intervention

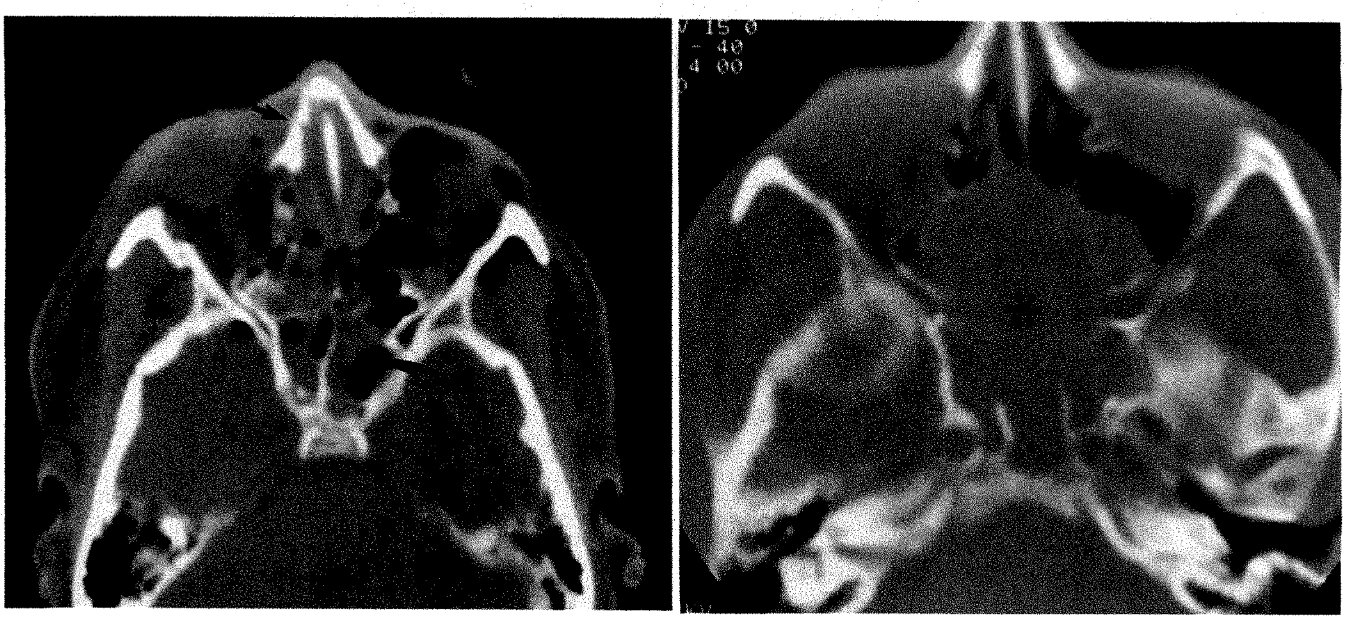

Fig 9.—Axial computed tomographic scans through the skull base, photographed at a bone window setting, at the time of initial injury (left) and at the time of visual loss 10 months later (right) in patient 4. Note the extensive fractures (single arrows), fluid-filled ethmoid and sphenoid sinuses (curved arrows), and small right epidural hematoma containing air (double arrows). The scan at right shows a soft-tissue mass (asterisk) replacing the ethmoid air cells and sphenoid sinus with resorption of the bony septa.

and significant visual recovery in five of six patients with aneurysm or fistula. Visual loss due to carotid-cavernous fistula results most frequently from accompanying glaucoma[15] and less frequently from a form of venous stasis/hypoxic retinopathy.[16-18] In either instance, visual loss may be gradual and delayed. Patient 1 in our series had delayed, but reversible, visual loss due to optic nerve and chiasmal compression from a massively dilated cavernous sinus. Trapping of his fistula with detachable intra-arterial balloons resulted in immediate collapse of the venous pouch and return of vision from 20/400 OD to 20/25 OD within 18 hours, implicating intracranial optic nerve compression, rather than ischemia, as the most probable cause of visual loss. Similar cases have been reported by Dandy and Follis.[19] Hedges et al[7] noted rapid return of visual function after collapse of a fistula using detachable balloons. In their series of 155 patients with carotid cavernous fistulas, Halbach et al[5] identified 21 patients with varices of the cavernous sinus extending into the suprasellar cistern. Details of the visual examination were not given. Three patients experienced fatal subarachnoid hemorrhage, and the authors considered the presence of a varix to be an indication for urgent treatment.

Patient 2 in our series also had delayed visual loss related to a direct carotid cavernous fistula. Angiography suggested extrinsic compression of the superior ophthalmic vein, and the CT scan confirmed the presence of a mass at the orbital apex. This mass had not been seen on prior studies, and we presume that it represented a hematoma compressing the optic nerve, although this radiographic appearance might have been produced by thrombosis of the superior ophthalmic vein. The presence of very low intraocular pressure also suggests the possibility of ophthalmic artery compromise with optic nerve ischemia. Optic nerve ischemia could have been caused by the apical orbital hematoma compressing the ophthalmic artery, although the ophthalmic artery appeared to be of normal caliber angiographically, or by sudden hypotension in the carotid-ophthalmic circulation associated with the episode of epistaxis. The optic disc swelling could, therefore, have been due to compression, ischemia, or ocular hypotony. A case of acute retrobulbar optic nerve ischemia has, in fact, been documented at autopsy in a patient with a carotid cavernous fistula,[18] and we cannot rule out an ischemic component to our patient's visual loss.

Patients 3 through 6 suffered delayed visual loss due to compressive optic neuropathy related to an aneurysm or pseudoaneurysm of the internal carotid artery. In patients 3, 5, and 6, the optic nerve and/or chiasm was directly compressed by the aneurysm. In patient 4, the optic nerve was compressed by an extradural intracranial hemorrhage arising from the pseudoaneurysm. In patients 3 through 5, the pseudoaneurysm arose from the medial portion of the horizontal segment of the carotid siphon, where it is in close approximation to the sphenoid sinus. Epistaxis may be a premonitory sign of damage to the carotid artery at this location and is usually related to extension of the vascular lesion into the sphenoid sinus.[8,9,11-13] Forty-six percent of the cases of carotid pseudoaneurysm reviewed by Chambers et al[8] had their first episode of epistaxis more than 1 month after trauma, and 13% had their first episode at least 6 months after trauma. As pointed out by several authors, this symptom merits thorough investigation in patients with a history of previous head injury.[8,9,11-13,20] In patients 3 and 4, growth of the pseudoaneurysm presumably occurred over intervals of 12 years and 8 months, respectively. This slow growth was reflected in the radiologic appearance of the lesion, with concentric lamination and expansion of adjacent bone. More rapid expansion of the lesion may cause acute visual loss due to extradural hemorrhage within the periarterial tissue. Finally, although delayed epistaxis after head trauma has been considered a warning sign of pseudoaneurysm by most authors, patient 2 in our series demonstrates the fact that delayed epistaxis may also occur in patients with carotid-cavernous fistulas. This sign has also been noted by Halbach et al.[5]

In a comprehensive review of the literature, Chambers et al[8] found reports of 96 patients with the syndrome of delayed epistaxis and immediate (not delayed) monocular blindness due to traumatic pseudoaneurysms of the cavernous internal carotid artery. The authors added four similar cases of their own. One patient presented with epistaxis 40 years after his head trauma. The authors reported a mortality of 30%, with no antemortem diagnosis in 15% of patients and a delay in diagnosis of 4 months or more after epistaxis in 73% of patients. They suggest that more frequent use of carotid arteriography in patients with delayed epistaxis might help to reduce the morbidity and mortality.

Although delayed visual loss was not mentioned in the report of Chambers et al,[8] we are aware of two other reports documenting this complication of traumatic pseudoaneurysms of the internal carotid artery.[12,13] Unfortunately, detailed visual information is not provided in either report. Successful treatment in two of our patients was accomplished by parent artery occlusion with intra-arterial balloons. Elective exclusion of the pseudoaneurysm from the circulation, keeping the artery patent by using an endovascular balloon technique, is preferred when possible. Permanent occlusion of the carotid artery is, nevertheless, recognized as a valid alternative when the morphologic configuration of the pseudoaneurysm does not allow selective treatment.[20] Prior to permanent occlusion of the parent artery, temporary occlusion is performed to determine the patient's tolerance for this procedure.

Patients 2 through 6 in this series had either a fistula or the neck of an aneurysm arising from the medial aspect of the intracavernous portion of the carotid artery siphon. It is unclear why some patients with trauma to this area form carotid-cavernous fistulas while others form pseudoaneurysms. Critical factors determining the type of lesion may include the extent of injury to the various layers of the arterial wall as well as the topographic relationship of the carotid artery to the dural wall of the cavernous sinus and to the bony wall of the sphenoid sinus. Although there were no obvious differences in the site of carotid trauma or the vascular anatomy in our six patients, individual variations in the relationship of the carotid artery to both the cavernous sinus and the sphenoid sinus are well described and are relatively common.[21] If the damaged segment of the arterial wall closely approximates the bony wall of the sphenoid sinus without interposition of the cavernous sinus, or if the artery is surrounded by a hematoma that effectively isolates it from the cavernous sinus, a traumatic aneurysm may be more likely to develop. When the segment containing the arterial tear is completely contained within the cavernous sinus, a fistula is more likely, especially if all layers of the arterial wall are involved. An aneurysm can still develop at this location when the damage to the arterial wall does not involve all layers. Traumatic rupture of small meningeal branches in the cavernous sinus can also result in a fistula supplied by the internal carotid artery or by dural collateral blood flow originating from the external carotid artery. The exact site of the arterial lesion, the configuration of the artery within the cavernous sinus, and its relationship to the sphenoid bone and sinus are all probably important in determining the type of lesion that results when the intracavernous carotid artery is injured.

Clinicians should be highly suspicious of carotid artery injury in patients with severe fractures of the sphenoid and ethmoid sinuses. Clinical and radiologic investigation of these patients should be sufficiently complete to rule out a traumatic carotid aneurysm or a direct carotid-cavernous fistula. A traumatic aneurysm should be suspected in any patient who develops delayed posttraumatic visual loss, even when the visual loss is contralateral to the side of the initial trauma. Intervention may be indicated even in cases with very long intervals between the time of initial trauma and the recognition of compressive optic neuropathy, regardless of the severity of the visual loss or the presence of optic disc pallor.

This project was supported, in part, by an unrestricted grant from Research to Prevent Blindness Inc, New York, NY.

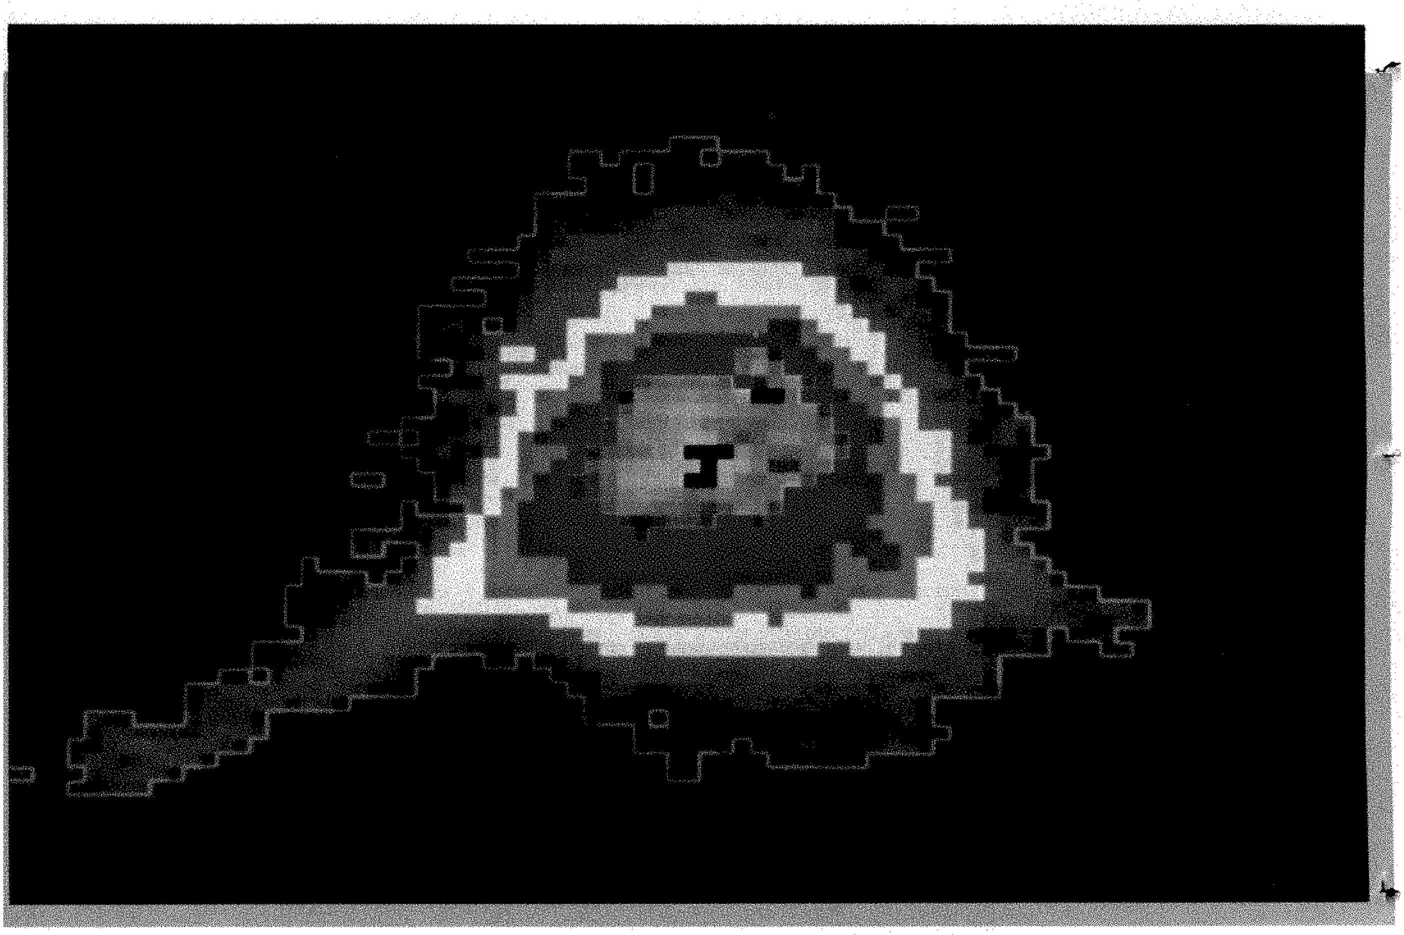
Current hypotheses suggest

Calcium influx is a key component of ischemic injury[1-4]

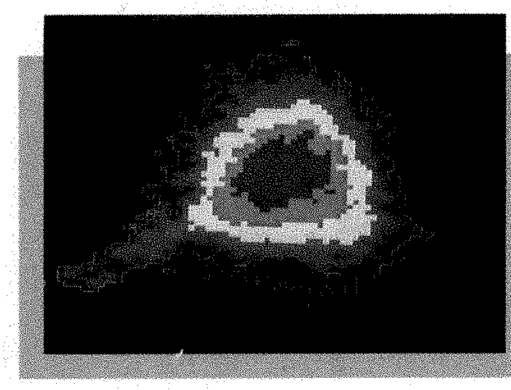


Photomicrograph of depolarized cultured rat hippocampal neuron, showing elevated intracellular calcium. Blue represents lowest and gray represents highest concentration of metabolically active ionized calcium.

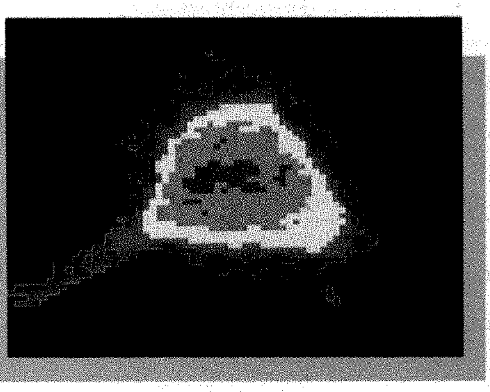
Ischemia is associated with calcium influx which activates phospholipases and degrades neuronal cell membranes[2-4]

Cerebroselective calcium channel blockade may protect against ischemic injury

NIMOTOP modulates calcium influx to promote cerebral perfusion and may directly protect neurons[5-7]



Nimodipine-treated cultured rat hippocampal neuron under depolarizing conditions, showing decreased intracellular calcium.



Cultured rat hippocampal neuron showing normal intracellular calcium[8]

BRIEF SUMMARY
NIMOTOP® (nimodipine/Miles) CAPSULES
For Oral Use

INDICATIONS AND USAGE

Nimotop® (nimodipine) is indicated for the improvement of neurological deficits due to spasm following subarachnoid hemorrhage from ruptured congenital intracranial aneurysms in patients who are in good neurological condition post-ictus (e.g. Hunt and Hess Grades I-III). Oral Nimotop® therapy should begin within 96 hours of the subarachnoid hemorrhage and continue for 21 days.

CONTRAINDICATIONS

None known.

PRECAUTIONS

General: Blood Pressure: Nimodipine has the hemodynamic effects expected of a calcium channel blocker, although they are generally not marked. In patients with subarachnoid hemorrhage given Nimotop® in clinical studies, about 5% were reported to have had lowering of the blood pressure and about 1% left the study because of this (not all could be attributed to nimodipine). Nevertheless, blood pressure should be carefully monitored during treatment with Nimotop® based on its known pharmacology and the known effects of calcium channel blockers.

Hepatic Disease: The metabolism of Nimotop® is decreased in patients with impaired hepatic function. Such patients should have their blood pressure and pulse rate monitored closely and should be given a lower dose (see Dosage and Administration).

Laboratory Test Interactions: None known.

Drug Interaction: It is possible that the cardiovascular action of other calcium channel blockers could be enhanced by the addition of Nimotop®.

In Europe, Nimotop® was observed to occasionally intensify the effect of antihypertensive compounds taken concomitantly by patients suffering from hypertension: this phenomenon was not observed in North American clinical trials.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study, higher incidences of adenocarcinoma of the uterus and Leydig-cell adenoma of the testes were observed in rats given a diet containing 1800 ppm nimodipine (equivalent to 91 to 121 mg/kg/day nimodipine) than in placebo controls. The differences were not statistically significant; however, the higher rates were well within historical control range for these tumors in the Wistar strain. Nimodipine was found not to be carcinogenic in a 91-week mouse study but the high dose of 1800 ppm nimodipine-in-feed (546 to 774 mg/kg/day) shortened the life expectancy of the animals. Mutagenic studies, including the Ames, micronucleus and dominant lethal tests were negative.

Nimodipine did not impair the fertility and general reproductive performance of male and female Wistar rats following oral doses of up to 30 mg/kg/day when administered daily for more than 10 weeks in the males and 3 weeks in the females prior to mating and continued to day 7 of pregnancy. This dose in a rat is about 4 times the equivalent clinical dose of 60 mg q4h in a 50 kg patient.

Pregnancy: Pregnancy Category C. Nimodipine has been shown to have a teratogenic effect in Himalayan rabbits. Incidences of malformations and stunted fetuses were increased at oral (by gavage) doses of 1 and 10 mg/kg/day administered from day 6 through day 18 of pregnancy but not at 3.0 mg/kg/day in one of two identical rabbit studies. In the second study an increased incidence of stunted fetuses was seen at 1.0 mg/kg/day but not at higher doses. Nimodipine was embryotoxic, causing resorption and stunted growth of fetuses, in Long Evans rats at 100 mg/kg/day administered by gavage from day 6 through day 15 of pregnancy. In two other rat studies, doses of 30 mg/kg/day nimodipine administered by gavage from day 16 of gestation and continued until sacrifice (day 20 of pregnancy or day 21 post partum) were associated with higher incidences of skeletal variation, stunted fetuses and stillbirths but no malformations. There are no adequate and well controlled studies in pregnant women to directly assess the effect on human fetuses. Nimodipine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Nimodipine and/or its metabolites have been shown to appear in rat milk at concentrations much higher than in maternal plasma. It is not known whether the drug is excreted in human milk. Because many drugs are excreted in human milk, nursing mothers are advised not to breast feed their babies when taking the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Adverse experiences were reported by 92 of 823 patients with subarachnoid hemorrhage (11.2%) who were given nimodipine. The most frequently reported adverse experience was decreased blood pressure in 4.4% of these patients. Twenty-nine of 479 (6.1%) placebo treated patients also reported adverse experiences. The events reported with a frequency greater than 1% are displayed below by dose.

DOSE q4h
Number of Patients (%)

	Nimodipine					Placebo
Sign/Symptom	**0.35 mg/kg (n = 82)**	**30 mg (n = 71)**	**60 mg (n = 494)**	**90 mg (n = 172)**	**120 mg (n = 4)**	**(n = 479)**
Decreased Blood Pressure	1 (1.2)	0	19 (3.8)	14 (8.1)	2 (50.0)	6 (1.2)
Abnormal Liver Function Test	1 (1.2)	0	2 (0.4)	1 (0.6)	0	7 (1.5)
Edema	0	0	2 (0.4)	2 (1.2)	0	3 (0.6)
Diarrhea	0	3 (4.2)	0	3 (1.7)	0	3 (0.6)
Rash	2 (2.4)	0	3 (0.6)	2 (1.2)	0	3 (0.6)
Headache	0	1 (1.4)	6 (1.2)	0	0	1 (0.2)
Gastrointestinal Symptoms	2 (2.4)	0	0	2 (1.2)	0	0
Nausea	1 (1.2)	1 (1.4)	6 (1.2)	1 (0.6)	0	0
Dyspnea	1 (1.2)	0	0	0	0	0
EKG Abnormalities	0	1 (1.4)	0	1 (0.6)	0	0
Tachycardia	0	1 (1.4)	0	0	0	0
Bradycardia	0	0	5 (1.0)	1 (0.6)	0	0
Muscle Pain/Cramp	0	1 (1.4)	1 (0.2)	1 (0.6)	0	0
Acne	0	1 (1.4)	0	0	0	0
Depression	0	1 (1.4)	0	0	0	0

There were no other adverse experiences reported by the patients who were given 0.35 mg/kg q4h, 30 mg q4h or 120 mg q4h. Adverse experiences with an incidence rate of less than 1% in the 60 mg q4h dose group were: hepatitis; itching; gastrointestinal hemorrhage; thrombocytopenia; anemia; palpitations; vomiting; flushing; diaphoresis; wheezing; phenytoin toxicity; lightheadedness; dizziness; rebound vasospasm; jaundice; hypertension; hematoma.

Adverse experiences with an incidence rate less than 1% in the 90 mg q4h dose group were: itching; gastrointestinal hemorrhage; thrombocytopenia; neurological deterioration; vomiting; diaphoresis; congestive heart failure; hyponatremia; decreasing platelet count; disseminated intravascular coagulation; deep vein thrombosis.

As can be seen from the table, side effects that appear related to nimodipine use based on increased incidence with higher dose or a higher rate compared to placebo control, included decreased blood pressure, edema and headaches which are known pharmacologic actions of calcium channel blockers. It must be noted, however, that SAH is frequently accompanied by alterations in consciousness which lead to an under reporting of adverse experiences. Patients who received nimodipine in clinical trials for other indications reported flushing (2.1%), headache (4.1%) and fluid retention (0.3%), typical responses to calcium channel blockers. As a calcium channel blocker, nimodipine may have the potential to exacerbate heart failure in susceptible patients or to interfere with A-V conduction, but these events were not observed.

No clinically significant effects on hematologic factors, renal or hepatic function or carbohydrate metabolism have been causally associated with oral nimodipine. Isolated cases of non-fasting elevated serum glucose levels (0.8%), elevated LDH levels (0.4%), decreased platelet counts (0.3%), elevated alkaline phosphatase levels (0.2%) and elevated SGPT levels (0.2%) have been reported rarely.

OVERDOSAGE

There have been no reports of overdosage from the oral administration of Nimotop®. Symptoms of overdosage would be expected to be related to cardiovascular effects such as excessive peripheral vasodilation with marked systemic hypotension. Clinically significant hypotension due to Nimotop® overdosage may require active cardiovascular support. Norepinephrine or dopamine may be helpful in restoring blood pressure. Since Nimotop® is highly protein-bound, dialysis is not likely to be of benefit.

DOSAGE AND ADMINISTRATION

Nimotop® is given orally in the form of ivory colored, soft gelatin 30 mg capsules for subarachnoid hemorrhage.

The oral dose is 60 mg (two 30 mg capsules) every 4 hours for 21 consecutive days. Oral Nimotop® therapy should commence within 96 hours of the subarachnoid hemorrhage.

If the capsule cannot be swallowed, e.g., at the time of surgery, or if the patient is unconscious, a hole should be made in both ends of the capsule with an 18 gauge needle, and the contents of the capsule extracted into a syringe. The contents should then be emptied into the patient's *in situ* naso-gastric tube and washed down the tube with 30 mL of normal saline (0.9%).

Patients with hepatic failure have substantially reduced clearance and approximately doubled C_{max}. Dosage should be reduced to 30 mg every 4 hours, with close monitoring of blood pressure and heart rate.

Acute Pseudobulbar or Suprabulbar Palsy

G. Besson, MD; J. Bogousslavsky, MD; F. Regli, MD; P. Maeder, MD

• We studied 13 patients with supranuclear lower cranial nerve ("pseudobulbar" or "suprabulbar") palsy of acute onset. While seven patients had had a prior stroke, six patients had no history of stroke. Eight patients experienced a complete bilateral supranuclear lower cranial nerve palsy, which was isolated in five patients and associated with hemiplegia and with hemiparesis in three patients. Pseudobulbar palsy was partial in five patients. Only one patient had neuropsychologic impairment. The pseudobulbar features improved or recovered within a few weeks in all patients. The common characteristic of the lesions on computed tomography or magnetic resonance imaging was the interruption of the corticonuclear pathways contrasting with marked sparing of the corticospinal pathways in both hemispheres. These lesions were either an opercular infarct, or a deep infarct in the corona radiata or internal capsule, or a lenticular hemorrhage. Hypertension was the most prevalent concomitant. Our findings suggest that acute pseudobulbar or suprabulbar palsy has rather stereotyped anatomic-vascular correlates and time course.

(*Arch Neurol.* 1991;48:501-507)

The term *pseudobulbar palsy* was coined in 1877 by Lépine[1] to differentiate lower cranial nerve palsy induced by supranuclear lesions from bulbar palsy related to bulbar nuclei lesions. Supranuclear lesions included corticobulbar and corticopontine pathway lesions. However, in 1837, Magnus[2] reported the first case of pseudobulbar palsy due to multiple infarcts and a few other cases have also been reported.[3,4] Several clinical and anatomic studies were performed at the beginning of the 20th century, and in his 1929 thesis Thurel[5] summarized the current knowledge at that time. He divided pseudobulbar palsy into three forms. The cortical form (Foix-Chavany-Marie syndrome[6]) was characterized by a faciopharyngoglossomasticatory diplegia with automatic voluntary dissociation. In the striatal form, the same features were associated with pyramidal signs, emotional lability, and intellectual impairment. The pontine form was characterized by faciopharyngoglossomasticatory diplegia associated with emotional lability, pyramidal and sometimes cerebellar signs, and by a lack of dementia. The term *pseudobulbar* was descriptive. In 1940, Langworthy and Hesser[7] coined the term *supranuclear bulbar paralysis* with reference to the suprabulbar location of lesions. Because the facial nucleus and the trigeminal motor nucleus are in the pons and patients may present facial diplegia or masticatory palsy, the terms *supranuclear pontobulbar palsy* or *corticobulbopontine palsy* are more appropriate. It may be easier to use the term *suprabulbar palsy*, as suggested by Loeb et al.[8] However, contrary to pseudobulbar all these terms fail to identify the bulb as the location of the symptoms. Also due to historic reasons, the term *pseudobulbar* is more widely used than *suprabulbar*.

In most patients, pseudobulbar palsy developed by fits and starts in relation to multiple recurrent strokes. We studied 13 patients in whom pseudobulbar palsy developed acutely.

PATIENTS AND METHODS

Patients were identified among 1800 stroke patients from the prospective Lausanne (Switzerland) Stroke Registry.[9] Seven patients had had a stroke prior to acute pseudobulbar palsy (group 1), while in six patients, acute pseudobulbar palsy developed without prior stroke (group 2). Computed tomography (CT) or magnetic resonance imaging (MRI) were performed in all patients, as well as extracranial Doppler ultrasound, electrocardiogram, standard blood tests, and neuropsychologic examination with a standard battery of tests.[10] Transcranial Doppler ultrasounds were performed in seven patients and cerebral angiography (Seldinger technique) was performed in one patient. Bidimensional echocardiography was performed in three patients. Vascular concomitants, such as hypertension (blood pressure higher than 160/90 mm Hg at least twice before the stroke), diabetes mellitus (fasting serum glucose concentration higher than 5.6 mmol/L), hypercholesterolemia (cholesterol higher than 6.5 mmol/L), and history of cigarette smoking were analyzed following the guidelines of the Lausanne Stroke Registry.[9]

REPORT OF CASES

CASE 1.—A 79-year-old man with a history of hypertension, atrial fibrillation, and aortic valve prosthesis experienced a left central facial paresis, which recovered over 1 month. A year later, he suddenly developed dysphagia and dysarthria. On admission, his blood pressure was 250/130 mm Hg. A left lower facial weakness was noted, while facial sensation was normal and corneal reflexes were symmetrical. We noted that his soft palate drooped bilaterally and the gag reflex was absent. Tongue movements were slowed with impaired protrusion. Examination of the sternocleidomas-

toid and trapezius muscles was normal. Jaw reflex was brisk. The patient was dysarthric and had a hypernasal voice. He chewed and swallowed with difficulty. No motor or sensory deficit was present in the limbs and trunk. Plantar responses were flexor. Results of a neurologic examination, 2 weeks after the onset, were normal.

Case 2.—A 71-year-old hypertensive and diabetic woman experienced right-sided weakness lasting for 30 minutes. A month later, she suddenly developed right-sided weakness and numbness that improved during the following day. The next morning, she lost consciousness and fell down. On awakening, she had a left-sided sensory-motor hemiparesis. On admission, her blood pressure was 210/100 mm Hg. Left lower facial weakness was noted. Sensory examination of her face and mouth was normal and corneal reflexes were symmetrical. The voice was low pitched, but there was no dysarthria. Pharyngeal motility, gag reflex, and swallowing were normal. Tongue movements were slowed and limited in range. Examination of the sternocleidomastoid and trapezius muscles was unremarkable. Jaw and palmomental reflexes were brisk. Left-sided spastic hemiparesis with brisk tendon reflexes and Babinski's sign was present. Sensation was decreased for touch, pinprick, position sense, graphesthesia, and pallesthesia on the left side. The patient was discharged after 2 weeks with only a persisting left hemiparesis.

Case 3.—A 40-year-old woman suffered a stroke with left hemiplegia. One year later, she was hospitalized in another institution for clonic movements of the lips followed by a generalized tonicoclonic seizure. On admission, 5 days after the seizure, her blood pressure was 130/80 mm Hg. Neurologic examination showed a severe facial diplegia, the mouth was open and she dribbled. Jaw reflex was brisk. Facial and buccal sensation were normal. The soft palate was immobile and the gag reflex was absent. She was unable to chew, to swallow, to speak, or to protrude her tongue. The sternocleidomastoid muscle was bilaterally weak. She had episodes of laughing and crying. The rest of the neurologic examination showed a left spastic hemiparesis with brisk tendon reflexes and Babinski's sign. She was discharged 6 weeks after the onset with only a mild improvement of the facial diplegia.

Case 4.—A 70-year-old hypertensive woman was admitted for sudden headaches followed by dysphagia and dizziness. Eight years before, she had experienced a left hemiplegia with left-sided sensory impairment. The hemiplegia had completely recovered, but she continued to complain of pins and needles sensation on the left side. On admission, her blood pressure was 190/120 mm Hg. Corneal reflex and facial pain and temperature sensation were decreased on the left side. Left lower facial weakness was present. Examination of the palate and tongue was normal, but she was unable to swallow and frequently coughed on her saliva. The gag reflex was present. The sternocleidomastoid and trapezius muscles were normal. The remainder of the neurologic examination showed mild weakness of the left arm and leg, brisk tendon reflexes, and left-sided Babinski's sign. The patient was discharged 4 weeks after the onset with a mild dysphagia.

Case 5.—A 74-year-old man with a history of hypertension, diabetes mellitus, and hypercholesterolemia was admitted for sudden dysarthria and dysphagia. Two years before, he had been seen in our department for a right ataxic hemiparesis. On cranial nerve examination at that time, he had rightward deviation of the tongue on protrusion. Computed tomography showed a small, deep infarct in the left capsulothalamic area. Six months later, he was readmitted for a right motor hemiparesis. Computed tomography showed a second small infarct in the medial part of the left corona radiata. Clinical recovery was complete and the patient remained asymptomatic for 18 months. On the present admission, his blood pressure was 170/100 mm Hg. Left lower facial weakness was present, while sensory examination of face was normal. He had severe dysphagia and dysarthria. The soft palate was weak bilaterally. Examination of the tongue, trapezius, and sternocleidomastoid muscles was normal. He had left mild hemiparesis without Babinski's sign. The patient recovered from the hemiparesis within 2 months, while the other signs persisted.

Case 6.—A 76-year-old hypertensive diabetic man with a history of shunted hydrocephalus developed a right hemiparesis. Cranial nerve examination was normal, CT showed a left capsular infarct. He was left with mild hemiparesis until 4 years later when he was admitted for sudden dysphagia and dysarthria. On admission, his blood pressure was 160/100 mm Hg. Neurologic examination showed facial diplegia without facial sensory abnormality or corneal reflex asymmetry. The jaw reflex was very brisk. The soft palate drooped bilaterally, more so on the left side, and the gag reflex was abolished. The patient was unable to chew and to swallow, and he had severe dysarthria. On protrusion, the tongue deviated to the left. The left hemiparesis was still present and plantar response was extensor bilaterally. The patient was discharged after 2 months with persisting facial diplegia, bilateral soft-palate weakness, and dysarthria.

Case 7.—A 73-year-old hypertensive man with a history of myocardial infarction suffered a left middle cerebral artery infarction with right sensory motor hemiplegia and aphasia. Angiography showed a 50% stenosis of the left internal carotid artery. Five years later, left internal carotid occlusion was discovered on a Doppler checkup. Nine years later, he was admitted for sudden mutism. On admission, his blood pressure was 170/90 mm Hg. Neurologic examination showed facial diplegia. Eye closure was weak, while the corneal reflex was asymmetric but present. The masticatory muscles were weak bilaterally. The patient's mouth remained open and he dribbled. He was mute and could not swallow. The jaw reflex was brisk. The palate was immobile and drooped. The gag reflex was absent. Tongue protrusion was markedly weak without deviation. Bilateral weakness of the sternocleidomastoid and trapezius muscles was present. The remainder of the neurologic examination was normal, including plantar responses. Two months after the onset, the patient could swallow and speak. His voice was dysarthric and all other signs persisted.

Case 8.—A 77-year-old hypertensive woman was admitted for sudden left hemiplegia. On admission, her blood pressure was 140/80 mm Hg. She had a vertical gaze paresis, while her horizontal gaze was normal. There was a left lower facial paresis without abnormal facial sensation. The soft palate was immobile and the gag reflex was absent. There was a leftward deviation of the tongue on protrusion. The left trapezius and sternocleidomastoid muscles were weak. Swallowing was impaired and the voice was hoarse. Left hemiplegia and right hemiparesis were present. Tendon reflexes were brisk and plantar responses were extensor bilaterally. The patient was discharged after 4 weeks. The left hemiplegia persisted unchanged, while the right hemi-

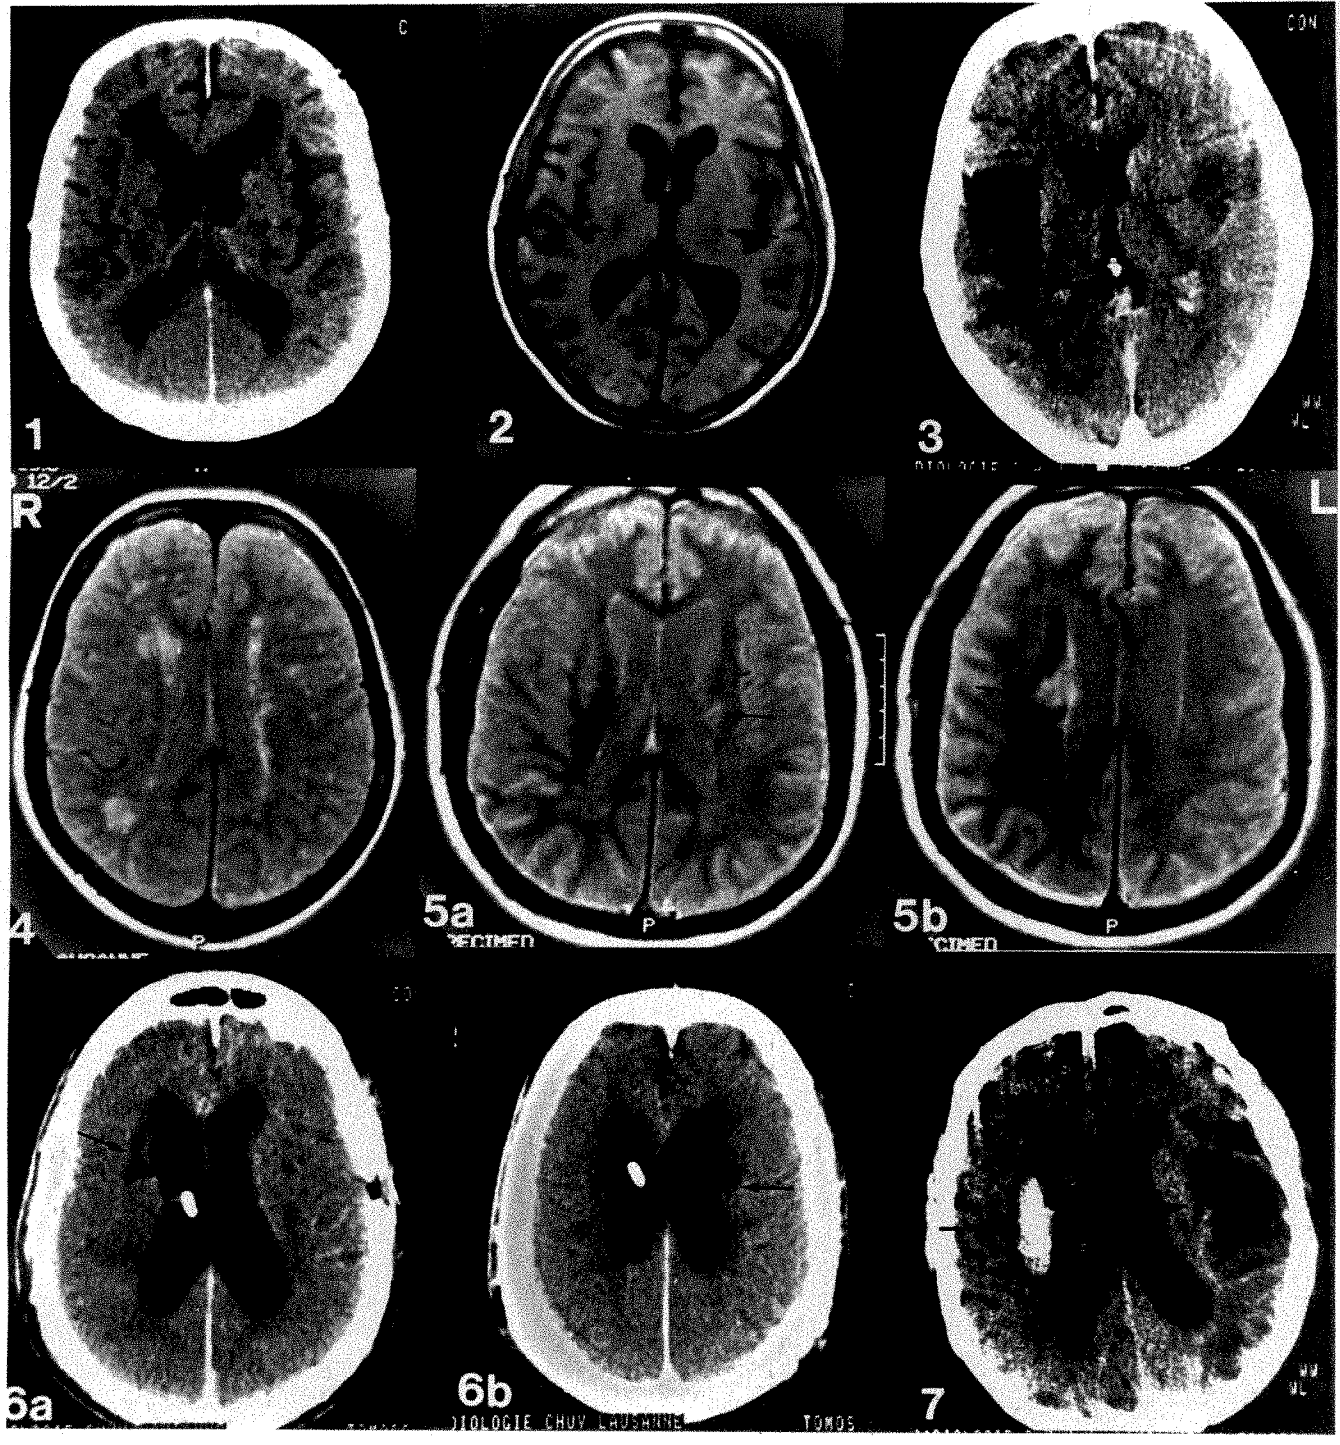

Fig 1.—Group 1. Computed tomographic or magnetic resonance imaging findings (R indicates right; L, left; and arrows point to the lesions). Number 1 through 7 refer to patients 1 through 7 mentioned in Table 1.

paresis and other signs improved.

Case 9.—A 55-year-old man experienced mild head trauma without loss of consciousness, but he subsequently complained of dysphagia and dysarthria. On admission, 8 days later, his blood pressure was 240/130 mm Hg. A right lower facial paresis was noted. Sensory examination of the face and soft palate was normal. Tongue movements were slowed and decreased in amplitude. Swallowing was difficult, but pharyngeal motility and gag reflex were normal. The patient had dysarthria and his voice was hypernasal. The remainder of the neurologic examination was normal, including plantar responses. The patient improved over 2 weeks and was discharged with persisting dysarthria.

Case 10.—A 71-year-old hypertensive woman experienced transient dysarthria. Two days later, she developed progressive left hemiparesis. One day later, she developed sudden dysarthria and severe dysphagia. On admission, her blood pressure was 140/90 mm Hg. Severe facial diplegia was present. The jaw reflex was brisk. Left facial hypesthesia for touch, pain, and temperature was present. The left corneal reflex was absent. The soft palate drooped bilaterally and the gag reflex was abolished. Tongue protrusion was slow and weak. The patient was dysarthric, with a low-pitched voice. She was unable to chew and to swallow. Left hemiparesis with brisk tendon reflexes and left-sided Babinski's sign was present. Pinprick and temperature sensa-

tion were reduced on the left side. The dysphagia completely recovered within 2 months, while mild hemiparesis and the other signs persisted.

Case 11.—A 63-year-old hypertensive woman had a 46-year history of left partial motor seizures starting in the left arm and sometimes followed by generalized clonic movements. She was admitted for sudden dysphagia and dysarthria. On admission, her blood pressure was 140/90 mm Hg. There was a facial diplegia. Her mouth remained open and she dribbled. The masseter muscles were weak. The jaw reflex was brisk. The soft palate drooped and she had decreased sensation on the right side. The gag reflex was absent. Motility of the vocal cords was normal on laryngeal examination. Tongue movements were severely limited in range and in strength. The patient was unable to chew and to swallow and her voice was low pitched and hypernasal. The rest of the neurologic examination was normal except for a mild left pronator drift. Plantar responses were bilaterally flexor. The patient improved over 3 weeks and was discharged with only a moderate left palate and lower facial paresis.

Case 12.—A 74-year-old hypertensive man with a history of myocardial infarction was admitted for sudden dysarthria and dysphagia. On admission, his blood pressure was 150/90 mm Hg. There was a bilateral lower facial paresis. The jaw reflex was brisk. Sensory examination of the face was unremarkable and the corneal reflex was normal. The soft palate was weak on the left side. The gag reflex was abolished. No tongue, trapezius, or sternocleidomastoid muscle weakness was present. Swallowing and chewing were impaired. His voice was dysarthric and low pitched. The rest of the neurologic examination was normal, in-

cluding plantar responses. The patient improved over 2 weeks and was discharged with persisting mild dysarthria.

Case 13.—An 81-year-old hypertensive man was admitted for sudden dysarthria. On admission, his blood pressure was 180/80 mm Hg. Bilateral facial paresis was present. He could not close his eyes voluntarily, while corneal reflex was normal. The jaw reflex was brisk. No sensory deficit was noted over the face. The soft palate was paralyzed, and the gag reflex was abolished. The patient was unable to speak, to swallow, to chew, or to move his tongue. The rest of the neurologic examination showed a right hemiplegia with right-sided Babinski's sign. The patient improved over 5 weeks and was left with mild paresis of the right hand and dysarthria.

RESULTS

CT and MRI Findings (Table 1)

In group 1 (Fig 1), bilateral small, deep infarcts were found in four patients, involving the rostral part of the posterior limb of the internal capsule in patients 1 and 2, and the corona radiata in patients 5 and 6. A bilateral superficial middle cerebral artery territory infarct involving the opercular region was found in patient 3. A superficial middle cerebral artery territory infarct was associated with a contralateral capsulolenticular hemorrhage in patient 7. In patient 4, multiple periventricular small, deep infarcts were found. The old previously asymptomatic lesion was a deep infarct in five patients (patients 1, 2, 4, 5, and 6) and was a superficial middle cerebral artery territory infarct in two patients (patients 3 and 7).

In group 2 (Fig 2), bilateral deep infarcts were found in three patients, involving the corona radiata in patient 8, the rostral part of the posterior limb of the internal capsule in patient 9, and the genu of the internal capsule in patient 12. A superficial middle cerebral artery infarct involving the opercular region was associated with a contralateral deep infarct in patients 10, 11, and 13.

Clinical Features (Table 2)

There were seven men and six women ranging in age from 40 to 81 years old. Five patients experienced an isolated complete faciopharyngoglossomasticatory palsy (patients 1, 6, 7, 11, and 12). Three patients experienced a faciopharyngoglossomasticatory palsy with hemiparesis (patients 3, 10, and 13). In five patients (patients 2, 4, 5, 8, and 9), the pseudobulbar palsy was only partial. One patient had involuntary laughing and crying (patient 3). None had trismus.

Neuropsychologic examination[10] was normal except in patient 2. This patient was unable to realize Luria conflicting tasks and sequential rhythms. The results of Raven PM 38 were abnormal (14 points). Recognition of face was impaired (15/27, Benton). Visual learning was severely impaired (23 of 40, learning of faces; 8 of 40, learning of countries).

The most common vascular concomitant was hypertension (11 of 13) (Table 3). Symptomatic heart disease was present in three patients, diabetes mellitus in three patients, and hypercholesterolemia in four patients. Extracranial Doppler ultrasound results showed internal carotid artery occlusion in two patients and was unremarkable in all other patients. Transcranial Doppler ultrasound results showed no detection of the right anterior cerebral artery in one patient and was normal in six patients.

COMMENT

Pseudobulbar or suprabulbar palsy developed acutely in all our patients. Although some patients have been presented,[11-17] the acute onset of pseudobulbar palsy is considered unusual. This acute onset may be explained by an acute damage to corticonuclear fibers on one side when contralateral corticonuclear fibers have been previously interrupted. This previous lesion may have been symptomatic (group 1) or asymptomatic (group 2). Actually, unilateral stroke limited to corticonuclear pathways may be asymptomatic if it is small and respects the corticospinal tract. When symptomatic, unilateral corticonuclear pathway damage usually produces only lower facial weakness. This may be explained by the classic notion that corticonuclear pathways project bilaterally toward cranial nerve nuclei, except to the lower facial nucleus.

Supranuclear innervation of the tongue may also be mainly unilateral. After his first stroke, patient 5 had a supranuclear palsy of the right XIIth cranial nerve associated with a small infarct in the medial part of the left corona radiata. Some other cases of deep lesions producing a supranuclear palsy of the XIIth cranial nerve have been described previously,[18-21] and 10% of small, deep infarcts of the carotid artery territory may have contralateral tongue paresis.[21] More uncommonly, patients with unilateral palatal palsy[22] or unilateral vocal cord palsy[23] have been described in association with a deep infarct involving corticonuclear pathways in the internal capsule or corona radiata. Trapezius or sternocleidomastoid muscle palsy has rarely been reported in pseudobulbar palsy.[24]

Three of our patients had XIth cranial nerve palsy, which was bilateral in two (patients 3 and 7) and unilateral in one (patient 8). In both patients with bilateral XIth cranial nerve palsy, one had superficial middle cerebral artery territory infarction on both sides and the other had a superficial middle cerebral artery territory infarct associated with a contralateral capsulolenticular hemorrhage. In the patient with unilateral left supranuclear XIth cranial nerve palsy, MRI showed a deep infarct in the posterior part of the right corona radiata near the lateral ventricule and a small, deep infarct in the medial part of the contralateral corona radiata. The supranuclear innervation to the XIth cranial nerve is controversial. Either a direct uncrossed innervation[25] or a double decussation[26] have been suggested. Patients with hemiplegia due to hemispheric lesions had weakness of the sternocleidomastoid muscle ipsilateral to the lesion,[27] which suggested that this muscle is controlled by the ipsilateral hemisphere. This is in contradiction with reports of presumed unilateral opercular syndrome with unilateral contralateral pseudobulbar palsy of the fifth, seventh, and ninth through XIIth cranial nerves.[24,28-31] However, none of these patients underwent autopsy, CT, or MRI studies. Rousseaux et al[32] have described a patient with unilateral facial, masseter, palatal, and pharyngeal palsy induced by a small infarct in the genu of the contralateral internal capsule. However the authors did not find sternocleidomastoid or trapezius muscle weakness, suggesting that the supranuclear pathway of the XIth cranial nerve was either spared or came from the ipsilateral hemisphere.

Five patients experienced an isolated faciopharyngoglossomasticatory palsy that has been mainly reported in bilateral frontal operculum lesions.[6,33-39] However, none of our patients had a bilateral operculum lesion on CT or MRI. In three patients, a bilateral deep infarct was found (patients 1, 6, and 12). A superficial middle cerebral artery infarct was associated with a contralateral deep infarct in one patient (patient 11) and with a contralateral lenticulocapsular hemorrhage in another patient (patient 7). A sixth patient experienced a faciopharyngoglossomasticatory palsy with unilateral mild hemiparesis in relation to a superficial middle cerebral artery infarct involving the operculum and contralateral deep infarct (patient 10). Bilateral faciopharyngoglossomasticatory palsy has rarely been reported with nonopercular lesions. In 1884, Raymond and Artaud[40] presented a 67-year-old man with faciopharyngoglossomasticatory palsy and mental impairment; a bilateral hemorrhage involved the lateral part of both lenticular nuclei and the anterior arm of both internal capsules. In 1898, Tournier[41] described a patient with bilateral faciopharyngoglossomasticatory palsy associated with trismus and left arm monoplegia; at autopsy, he found a right opercular infarct and two left deep infarcts involving the superomedial part of the thalamus and the lenticular nucleus. In 1979, Fisher[42] presented a patient (case 5) with faciopharyngoglossomasticatory palsy and mild right hemiparesis; at autopsy, he found bilateral deep infarcts situated in the genu of the internal capsules. In 1985, Leys et al[14] described a patient with bilateral faciopharyngoglossomasticatory palsy due to an infarct in the upper part of the genu of the internal capsule on both sides on CT. In 1988, Starkstein et al[43] presented a patient with bilateral faciopharyngoglossomasticatory palsy, aphemia, left hemiparesis, and left hemineglect; at autopsy, they found a unilateral infarct involving the right insula, while the left hemisphere, the brain stem, and the cerebellum appeared normal. These previous reports and our findings confirm that bilateral faciopharyngoglossomasticatory palsy may result from bilateral frontal operculum involvement, but they also suggest that bilateral damage to corticonuclear pathways sparing pyramidal pathways may not be uncommon.

Six patients had a pseudobulbar palsy produced by bilateral deep infarcts. However, only one had neuropsychologic impairment (patient 2) and none had forced laughing and crying, which have been usually reported in chronic pseudobulbar palsy from striatocapsular involvement. On the other hand, involuntary laughing and crying was present in one patient who had bilateral cortical infarcts (patient 3). Involuntary laughing and crying is uncommon in the chronic form of pseudobulbar palsy due to cortical lesions.[44] Involuntary laughing and crying is supposed to result from decreased inhibition over centers controlling emotional facial movements.[45] Centers and pathways involved in laughing and crying are yet unknown. Yarnell[46] postulated that involuntary laughing and crying in right-handed patients corresponded to a lesion interrupting connections between the right middle cerebral artery territory and the left pons. Recently, a patient with isolated involuntary laughing and crying induced by a small brainstem vascular malformation was described.[47] Lack of pseudobulbar sign suggested that corticonuclear tract lesions are not necessary to produce these symptoms.

The most prominent vascular concomitant was hypertension in our patients. Three patients (patients 1, 7, and 12) had a potential cardiac source of embolism. These three patients were also hypertensive, one had hypercholesterolemia (patient 1) and one was a smoker. Among these three patients, two had bilateral small, deep infarcts (patients 1 and 12) and one had a superficial middle cerebral artery territory infarct associated with a contralateral lenticulocapsular hemorrhage. Extracranial vascular abnormalities were found in two patients (patients 7 and 10) who were also hypertensive. Therefore, acute pseudobulbar palsy may identify a subgroup of patients in whom large-artery disease and cardioembolism are an unlikely cause for stroke.

Our findings suggest that acute pseudobulbar palsy, either with or without prior stroke, may be more common than what the recent literature suggests. It may be associated with infarct or hemorrhage involving the frontal opercular region or the corticonuclear pathways in both cerebral hemispheres, but largely sparing the corticospinal pathways.

This study was supported by grants from the Conseil Regional de la Région Rhône-Alpes, France.

We thank Jean Claude Gautier, MD; C. Miller Fisher, MD; and Louis R. Caplan, MD, for their helpful comments on the manuscript.

TECA DG32 *Redefining the shape of EEG*

In 1924 Hans Berger first recorded the electrical activity of the brain. EEG was born. Instruments were designed and developed, but from the mid 50's—almost 35 years—technology and equipment have remained the same ... ***Until now!*** *As a new decade dawns,* ***TECA*** *introduces the* ***DG32—the next dimension in EEG.***

The DG32 offers a variety of improved features and revolutionary techniques ... ***optical disc storage*** *dramatically reduces storage needs and allows easy remontaging and reformatting; high resolution* ***thermal printing*** *eliminates mess and the need to recalibrate;* ***comprehensive reporting*** *capabilities;* ***state of the art controls*** *and ergonomic design.*

The TECA DG32 is truly a breakthrough for EEG technology. Developed and manufactured in the USA by TECA Corporation—a leader in the neurodiagnostic industry, providing a full line of accessories and supplies, and backed by a nationwide network of service and support.

Regional Cerebral Blood Flow in Developmental Stutterers

Kenneth D. Pool, MD; Michael D. Devous, Sr, PhD; Frances J. Freeman, PhD;
Ben C. Watson, PhD; Terese Finitzo, PhD

• Stuttering is a poorly understood communication disorder with a 1% global prevalence. Recently, there has been a resurgence of interest in a neurogenic origin for the disorder, although no research has established clear neurological differences between "developmental" (stuttering onset in childhood) stutterers and nonstutterers. We have used xenon 133 single-photon emission computed tomography to study regional cerebral blood flow (rCBF) in 20 stutterers. Analysis revealed global, absolute flow reductions. Relative flow asymmetries (left < right) were identified in three hemispheric regions: anterior cingulate and superior and middle temporal gyri. Milder changes were found in the left inferior frontal gyrus. Stutterers had rCBF values below median for either anterior cingulate or middle temporal gyri. With one exception, severe stutterers had rCBF values below median for the anterior cingulate gyrus. All stutterers with rCBF values above median in the cingulate gyrus had rCBF values below median in the middle temporal gyrus, and severity of their disorder was either mild or moderate. Our findings suggest that stuttering is a neurogenic disorder involving recognized cortical regions of speech-motor control.

(*Arch Neurol.* 1991;48:509-512)

Stuttering is a disruption in the fluency of verbal expression characterized by involuntary audible or silent repetitions or prolongations in the utterance of short speech elements, eg, sounds, syllables, and words of one syllable.[1] According to Shames,[2] nearly 1% of American adults and children stutter. For one person in 300, stuttering constitutes a severe communication disorder.

Both psychogenic and neurogenic origins have been proposed for stuttering. In the 19th century, a number of authorities offered neurological theories of stuttering (as reviewed by Van Riper[3]). Kussmaul[4] viewed stuttering as an aphasia that produced a syllabic dysarthria characterized by a lack of coordination of voice, respiration, and articulation. Based on a series of case studies of aphasic (acquired) stuttering, Gutzmann[5] considered stuttering a result of a deficiency in the cerebral cortex that impaired syllabic coordination. In the 1980s, we have seen a reemergence of interest in stuttering secondary to nervous system damage, especially "acquired" stuttering subsequent to head trauma and stroke.[6] There remains, however, no conclusive evidence of a neurogenic basis for developmental (onset in childhood) stuttering.[7]

A number of current theories represent experimentally based elaborations of these early speculations, and they alternatively view stuttering as a sequencing and timing disorder,[8] as a temporal programming disorder,[9] as a prosodic disorder,[10] and as a cognitive-linguistic disorder.[11] In attempting to reconcile divergent stuttering theories, as well as experimental results, heterogeneous models have been proposed.[12] Recent evidence from studies of speech-motor control in stutterers provide some evidence that severe stutterers differ from mild and moderate stutterers along the parameters that could coincide with differences in underlying neuropathophysiologic causes.[13]

Alterations in brain function, as reflected by cerebral blood flow or metabolism, might provide a sensitive tool for elucidation of neurologic function in stuttering and for differentiation of clinical subgroups. Wood et al[14] investigated patterns of regional cerebral blood flow (rCBF) in two stutterers. Subjects read aloud while receiving and not receiving haloperidol medication. In both cases, stutterers showed reduced cortical blood flow to Broca's area compared with the homologous area of the right hemisphere while not receiving haloperidol. When the stuttering subjects were fluent (when taking haloperidol medication), greater flow was observed in the left hemisphere compared with the right.

The present article reports the rCBF patterns in 20 adult developmental stutterers who were studied using xenon 133 single-photon emission computed tomography (SPECT). The purpose of the study was to determine whether rCBF in stutterers differed from that in normal subjects and whether rCBF differences were related to differences in stuttering severity.

SUBJECTS AND METHODS

Subjects

Twenty adult stutterers (19 male and one female) provided informed consent to participate in this study according to the guidelines of our Institutional Review Board. Age of subjects ranged from 24 to 59 years (mean age, 37 years). Nine subjects began stuttering in early childhood (before age 5 years); nine subjects began in later childhood (between 5 and 12 years of age); and two subjects reported postpuberty onset. Twelve subjects reported a family history of stuttering. These 12 included one set of twins and one set of brothers. Not counting these siblings, eight subjects had a positive family history of stuttering. Two subjects were left-handed and 18 were right-handed. All subjects had received some form of speech therapy, ranging from a few ses-

sions to over 7 years of therapy. Five subjects were receiving speech therapy when studied.

Seventy-eight age-matched subjects selected from 97 previously described laboratory subjects[15] were used for comparison with the 20 stutterers. Laboratory control subjects had an average age of 33 years (range, 20 to 59 years), and they were screened by history for significant neurologic involvement including transient ischemic attack, stroke, head trauma, diabetes, hypertension, and psychiatric disorders. They were not taking any psychoactive medication. Absolute rCBF values in stutterers were compared with those in a gender-matched subgroup of 43 subjects with a mean age of 40 years (SD, 15 years). Flow ratios, which are not gender-sensitive, were examined for all 78 control subjects.

Mean Absolute Regional Cerebral Blood Flow (rCBF) Values in 78 Age-Matched Normal Control Subjects and 20 Stutterers

Region of Interest	Mean (SD) Absolute rCBF, mL/min/100g Normal Subjects	 Stutterers
L superior frontal	72 (15)	52 (10)

Fluency Evaluation

For all 20 stutterers, multiple fluency measures were analyzed using clinical behavioral assessments.[16,17] Percent dysfluency, duration of longest blocks, and secondary symptoms were used in global ratings of severity. When these three measures were considered, 10 of the 20 stutterers were classified as severe, four as moderate, and six as mild.

Magnetic Resonance Imaging

Magnetic resonance imaging scans were unrevealing for 19 of 20 stutterers. One subject's left cervical and intracavernous internal carotid artery could not be visualized. Possible explanations include occlusion or dissection or severe hypoplasia.

rCBF

The rCBF was measured quantitatively in three tomographic cross sections using the tomograph (Tomomatic 64 SPECT, Medimatic A/S, Copenhagen, Denmark), as described by Stokely et al.[18] This tomograph consists of four detector arrays, each containing 16 sodium iodide (thallium) scintillation crystals mounted in a hollow-square configuration that rotates about the subject's head at 6 rpm. Special focused collimators define three transverse tomographic sections with centers 4 cm apart. Xenon 133 was administered in an air/oxygen mixture (10 mCi/L) by inhalation during the first minute of a 4-minute wash-in/wash-out procedure. The subject breathes room air during the remaining 3 minutes of the study. During the tomographic measurement of the cerebral transit of xenon 133, activity in the lung is monitored by a scintillation probe placed over the right upper quadrant of the subject's chest. This lung activity is assumed to be proportional to the arterial blood concentration of xenon 133 arriving at the brain. Three tomographic cross sections are generated by filtered back-projection with attenuation correction, according to the method of Kay and Keyes.[19] The rCBF is calculated according to the double-integral method.[20-22] The lung curve is used as the input function to the Kanno-Lassen algorithm to compensate for delivery of tracer by inhalation rather than by direct injection into the internal carotid artery.[23] The rCBF images are displayed in a 64 × 64 matrix, employing a 16-shade scale adjusted to range from zero flow to maximum flow. Transverse resolution is 1.7 cm, and axial resolution is 1.9 cm.

Subjects were positioned in the tomograph using a face-marking template so that cross sections were obtained 2, 6, and 10 cm above and parallel to the canthomeatal line. They were studied in the supine position, with eyes open, and ears unplugged in a dimly lit room with background noise originating primarily from instrument cooling fans. Subjects breathed through a fitted mouthpiece while their nostrils were occluded by a spring clamp. An approximately 2-minute adaptation time was allowed prior to initiating the study. Each subject was asked to take a deep breath at the beginning of the study, after which no further communication occurred. These procedures and values in

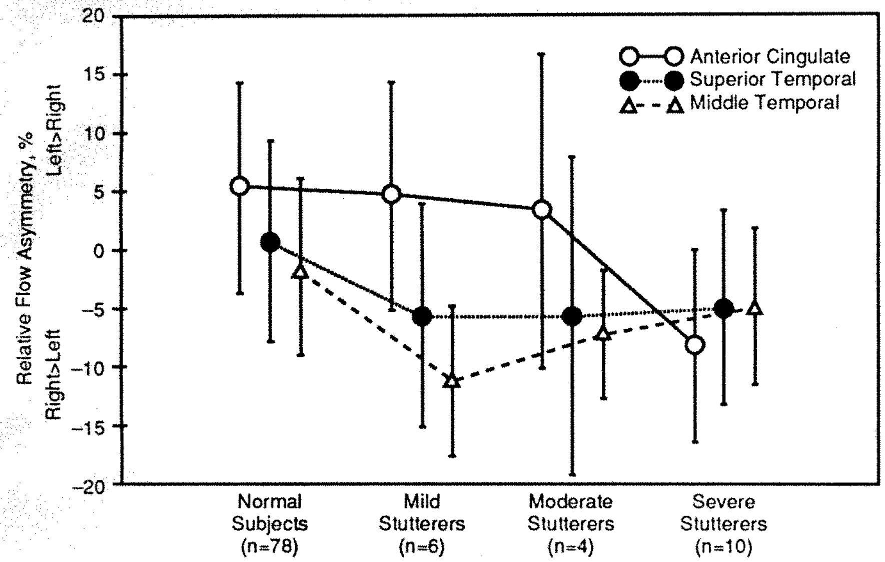

Fig 2.—Relative regional cerebral flow asymmetries by severity of stuttering.

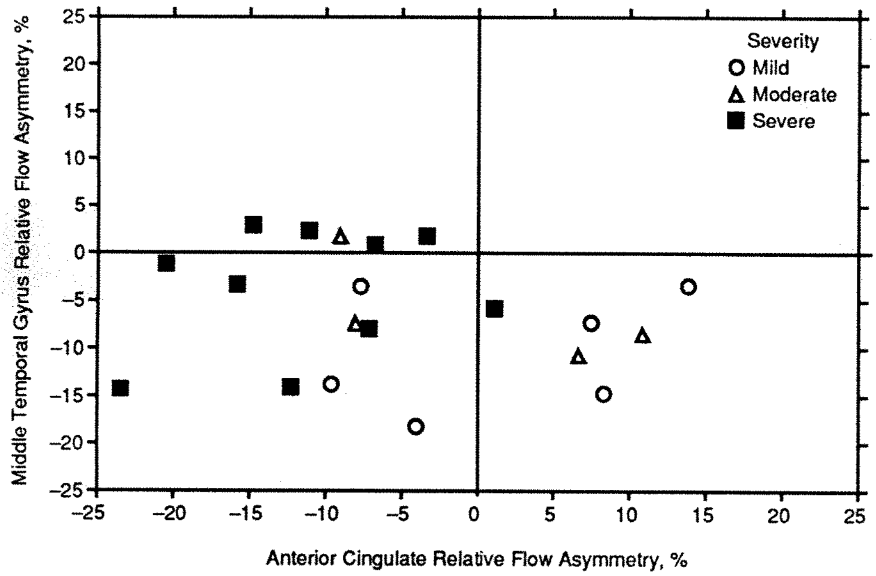

Fig 3.—Stuttering severity vs relative flow asymmetry of regional cerebral blood flow. All relative asymmetries are relative to median values in normal control subjects.

normal subjects, reproducibility, intersubject variability, and asymmetries have been described in detail by Devous et al.[15]

Quantitative rCBF Analyses

The rCBF images were transferred from the V77 computer (Univac) to a PE 3241 computer (Perkin-Elmer). This system, coupled to a graphics tablet (Talos Cybergraph) and a 512 × 512 × 8-bit frame buffer (Genisco GCT-3000) with a color monitor (Tektronix 670-A-1), is used with an interactive graphics software package to obtain rCBF values from images. Stokely et al[24] describe this analysis scheme in detail. Briefly, rCBF images are scaled, rotated, and translated to match a predefined standard brain outline that includes graphic overlay of regions of interest (ROIs) determined from a digitized atlas of CT and gross pathological specimens (individual CT data are not used). The only operator interface required is the identification of the positions of major and minor axes on an ellipse that is fit to the outer boundary of the rCBF image. Regional flows and their SDs are obtained from frontal, parietal, superotemporal, occipital, and central gray matter, as well as white matter and both hemispheres, using the section 6 cm above the canthomeatal line. Inferotemporal and cerebellar flows are obtained from the section 2 cm above the canthomeatal line. The automatic fitting routine produces standard scaling and reproducible ROIs so that operator intervention has a minimal effect on results. All visual and digitized flow data in the current study were generated from section two, 6 cm above the canthomeatal line, as this section best represents major cortical ROIs.

Flow values from ROI analyses were then normalized by dividing each region by the average flow to that hemisphere for both patients and 78 normal control subjects. Asymmetry was then calculated as (left ROI ratio − right ROI ratio) for both groups. Differences between stutterers and control subjects were examined by computing the asymmetry difference for the study subjects relative to the median value for control subjects for each region (referred to subsequently as *relative flow asymmetry*).

Statistical Analysis

Differences in absolute flow values between groups in 20 cortical ROIs were examined by sign test. Relative rCBF asymmetries were statistically corrected for multiple measures to determine if there were focal rCBF reductions in stuttering using multiple measurement t tests for small sample size. To achieve an experiment-wise significance of $P < .05$, the individual measure significance cutoff was set at $P < .005$.

RESULTS

The rCBF was globally reduced in stutterers (Table) compared with that in both age- and gender-matched normal control subjects (mean flow in stutterers below mean flow in normal control subjects for 20 of 20 atlas-derived cortical ROIs; sign test, $P < .0001$). Significant relative flow asymmetry (left < right) was found for the anterior cingulate (t[96] = 3.2; $P < .005$) and superior (t[96] = 2.8; $P < .005$) and middle temporal gyri (t[96] = 3.1; $P < .005$). Milder asymmetry was seen in the inferior frontal gyrus (t[96] = 2.3; $P < .01$). Results for all 10 asymmetry flow measures are shown in Fig 1.

Mean relative rCBF asymmetry in anterior cingulate and superior and middle temporal gyri for normal control subjects, and for mild, moderate, and severe stutterers is shown in Fig 2. Flow asymmetries are present in the superior and middle temporal gyri for all stutterers. While there is less asymmetry in the middle temporal gyrus for severe stutterers compared with mild and moderate subjects, this difference is not significant for group averaged data. Group average flow asymmetries in the anterior cingulate gyrus are limited to the severe stuttering group. The relationship of individual flow asymmetries to global perceptual stuttering severity is illustrated in Fig 3. All stutterers had flow asymmetry below median (left reduced relative to right) for either anterior cingulate or middle temporal gyri. All but one severe stutterer had below median value for the anterior cingulate gyrus. All stutterers with values above median in cingulate had values below median in the middle temporal gyrus and they were either mild or moderate stutterers.

COMMENT

An association between dysfluency in stuttering and cortical dysfunction in the left cingulate and left inferior frontal gyrus is consistent with classic anatomoclinical principles of speech-motor control. Motor initiation deficits have been localized to the mesiofrontal cortex in the region of the cingulate or supplementary motor area.[25] Motor programming for speech has been localized to the left perisylvian (inferior frontal) cortex.

But what of the finding of left temporal lobe hypoperfusion, especially in mild to moderate stutterers? The question of a relationship between stuttering and temporal lobe dysfunction has a long history. Auditory tests, including auditory electrophysiologic tests, have performed two functions in stuttering research: (1) as a measure of cerebral dominance for language and (2) in the search for abnormalities of the auditory feedback mechanism subserving speech production.[7] Unfortunately, while individual findings have often pointed to temporal lobe dysfunction,[26] or to auditory brainstem dysfunction,[27,28] the heterogeneity in stuttering often precluded significant results. Rosenfield and Jerger[7] acknowledged the conflicting evidence, but they did not discard persistent findings implicating the central auditory system. Our data support their contention that there may be a link to the temporal lobe in at least a subgroup of stutterers.

Further evidence for a role of temporal lobe involvement in speech-motor dysfunction was reported in three separate rCBF studies of children labeled dysphasic.[29-31] Hypoperfusion (and hence low metabolic activity) in cortical regions similar to those found herein was reported in all three studies. In a study by Denays et al,[29] two children with an expressive impairment demonstrated hypoperfusion in the left inferior frontal convolution, involving Broca's area. Billard et al[30] reported posterotemporal flow deficits in patients with primarily expressive deficits. Lou et al[31] reported frontal lobe and perisylvian hypoperfusion in their three patients with verbal dyspraxia. The similarity of these identified lesion sites and those reported herein to those expected in a known disorder of language like acquired aphasia reminds us of Kussmaul's aphasia/stuttering hypothesis, in which stuttering was described as an aphasia that produced a syllabic dysarthria characterized by a lack of coordination of voice, respiration, and articulation.

While we are far from unraveling the neuropathophysiologic origin of stuttering, these data provide intriguing preliminary evidence for cortical dysfunction in stutterers related to reduced and asymmetric left frontal and temporal perfusion. This study should be considered an exploratory data analysis. We are undertaking confirmatory research in a larger group of stutterers.

Funding for this project was provided by the National Institutes of Health (Bethesda, Md) grant NS 18276.

We are indebted to our colleagues Dianne Mendelsohn, MD, for interpretation of the magnetic resonance imaging studies and Steven D. Schaefer, MD, for laryngologic examinations. Mari Hayashi, MS, Sandra Chapman, PhD, Kay Stephens, MS, and James Dembowski, MS, conducted clinical studies, obtained case histories, and coordinated testing. Our doctoral students, Jackie Clark, Al Rampy, and Susan Reamy Rampy, assisted in data analysis.

PERMAX®
pergolide mesylate

An added dimension in the treatment of Parkinson's disease

An adjunct to levodopa/carbidopa in the management of patients with Parkinson's disease

- The first dopamine agonist indicated for Parkinson's disease with activity at both D_1 and D_2 receptors
- 10 to 1,000 times more potent than bromocriptine on a milligram-per-milligram basis
- Improves patients' functioning in activities of daily living, relieves signs and symptoms, and reduces "off" time
- May allow a significant reduction in levodopa dosage
- Most common adverse events were dyskinesia, nausea, dizziness, and hallucinations
- Hypotension may occur, especially early in the course of therapy
- Stepwise titration without regard to meals
- Available in 0.05-mg, 0.25-mg, and 1-mg scored tablets

Permax performs

Lilly

See adjacent page for prescribing information

Permax®

pergolide mesylate

Brief Summary. Consult the package insert for complete prescribing information.

Indications and Usage: Permax is indicated as adjunctive treatment to levodopa/carbidopa in the management of the signs and symptoms of Parkinson's disease.

Evidence to support the efficacy of pergolide mesylate as an antiparkinsonian adjunct was obtained in a multicenter study enrolling 376 patients with mild to moderate Parkinson's disease who were intolerant to levodopa/carbidopa as manifested by moderate to severe dyskinesia and/or on-off phenomena. On average, the sample of patients evaluated had been on levodopa/carbidopa for 3.9 years (range, two days to 16.8 years). The administration of pergolide mesylate permitted a 5% to 30% reduction in the daily dose of levodopa. On average, these patients treated with pergolide mesylate maintained an equivalent or better clinical status than they exhibited at baseline.

Contraindications: Pergolide mesylate is contraindicated in patients who are hypersensitive to this drug or other ergot derivatives.

Warnings: *Symptomatic Hypotension* —In clinical trials, approximately 10% of patients taking pergolide mesylate with levodopa vs 7% taking placebo with levodopa experienced symptomatic orthostatic and/or sustained hypotension, especially during initial treatment. With gradual dosage titration, tolerance to the hypotension usually develops. It is, therefore, important to warn patients of the risk, to begin therapy with low doses, and to increase the dosage in carefully adjusted increments over a period of three to four weeks.

Hallucinosis —In controlled trials, pergolide mesylate with levodopa caused hallucinosis in about 14% of patients as opposed to 3% taking placebo with levodopa. This was of sufficient severity to cause discontinuation of treatment in about 3% of those enrolled; tolerance to this untoward effect was not observed.

Fatalities —In the placebo-controlled trial, two of 187 patients treated with placebo died as compared with one of 189 patients treated with pergolide mesylate. Of the 2,299 patients treated with pergolide mesylate in premarketing studies evaluated as of October 1988, 143 died while on the drug or shortly after discontinuing the drug. The patient population under evaluation was elderly, ill, and at high risk for death. It seems unlikely that pergolide mesylate played any role in these deaths, but the possibility that pergolide shortens survival of patients cannot be excluded with absolute certainty.

In particular, a case-by-case review of the clinical course of the patients who died failed to disclose any unique set of signs, symptoms, or laboratory results that would suggest that treatment with pergolide caused their deaths. Sixty-eight percent (68%) of the patients who died were 65 years of age or over. No death (other than a suicide) occurred within the first month of treatment; most of the patients who died had been on pergolide for years. A relative frequency of the causes of death by organ system are: pulmonary failure/pneumonia, 35%; cardiovascular, 30%; cancer, 11%; unknown, 8.4%; infection, 3.5%; extrapyramidal syndrome, 3.5%; stroke, 2.1%; dysphagia, 2.1%; injury, 1.4%; suicide, 1.4%; dehydration, 0.7%; glomerulonephritis, 0.7%.

Precautions: *General* —Caution should be exercised when administering pergolide mesylate to patients prone to cardiac dysrhythmias.

In a study comparing pergolide mesylate and placebo, patients taking pergolide mesylate were found to have significantly more episodes of atrial premature contractions (APCs) and sinus tachycardia.

The use of pergolide mesylate in patients on levodopa may cause and/or exacerbate preexisting states of confusion and hallucinations (*see* Warnings). Also, the abrupt discontinuation of pergolide mesylate in patients receiving it chronically as an adjunct to levodopa may precipitate the onset of hallucinations and confusion; these may occur within a span of several days. Discontinuation of pergolide should be undertaken gradually whenever possible, even if the patient is to remain on levodopa.

The administration of pergolide mesylate to patients receiving levodopa may cause and/or exacerbate preexisting dyskinesia.

Information for Patients —Patients and their families should be informed of the common adverse consequences of the use of pergolide mesylate (*see* Adverse Reactions) and the risk of hypotension (*see* Warnings).

Patients should be advised to notify their physician if they become pregnant or intend to become pregnant during therapy.

Patients should be advised to notify their physician if they are breast feeding an infant.

Laboratory Tests —No specific laboratory tests are deemed essential for the management of patients on Permax. Periodic routine evaluation of all patients, however, is appropriate.

Drug Interactions —Dopamine antagonists, such as the neuroleptics (phenothiazines, butyrophenones, thioxanthines) or metoclopramide, ordinarily should not be administered concurrently with Permax (a dopamine agonist); these agents may diminish the effectiveness of Permax.

Because pergolide mesylate is approximately 90% associated with plasma proteins, caution should be exercised if pergolide mesylate is coadministered with other drugs known to affect protein binding.

Carcinogenesis, Mutagenesis, and Impairment of Fertility —A two-year carcinogenicity study was conducted in mice using dietary levels of pergolide mesylate equivalent to oral doses of 0.6, 3.7, and 36.4 mg/kg/day in males and 0.6, 4.4, and 40.8 mg/kg/day in females. A two-year study in rats was conducted using dietary levels equivalent to oral doses of 0.04, 0.18, and 0.88 mg/kg/day in males and 0.05, 0.28, and 1.42 mg/kg/day in females. The highest doses tested in the mice and rats were approximately 340 and 12 times the maximum human oral dose administered in controlled clinical trials (6 mg/day equivalent to 0.12 mg/kg/day).

A low incidence of uterine neoplasms occurred in both rats and mice. Endometrial adenomas and carcinomas were observed in rats. Endometrial sarcomas were observed in mice. The occurrence of these neoplasms is probably attributable to the high estrogen/progesterone ratio which would occur in rodents as a result of the prolactin-inhibiting action of pergolide mesylate. The endocrine mechanisms believed to be involved in the rodents are not present in humans. However, even though there is no known correlation between uterine malignancies occurring in pergolide-treated rodents and human risk, there are no human data to substantiate this conclusion.

Pergolide mesylate was evaluated for mutagenic potential in a battery of tests that included an Ames bacterial mutation assay, a DNA repair assay in cultured rat hepatocytes, a point-mutation assay in cultured L5178Y cells, and a determination of chromosome alteration in bone marrow cells of Chinese hamsters. A weak mutagenic response was noted in the in vitro mammalian cell-point-mutation assay using L5178Y cells only after metabolic activation with rat liver microsomes. No mutagenic effects were obtained in the two other in vitro assays and in the in vivo assay. The relevance of these findings to humans is unknown.

A fertility study in male and female mice showed that fertility was maintained at 0.6 and 1.7 mg/kg/day but decreased at 5.6 mg/kg/day. Prolactin has been reported to be involved in stimulating and maintaining progesterone levels required for implantation in mice and, therefore, the impaired fertility at high dose may occur because of depressed prolactin levels.

Usage in Pregnancy—Pregnancy Category B —Reproduction studies were conducted in mice at doses of 5, 16, and 45 mg/kg/day and in rabbits at doses of 2, 6, and 16 mg/kg/day. The highest doses tested in mice and rabbits were 375 and 133 times the 6 mg/day maximum human dose administered in controlled clinical trials. In these studies, there was no evidence of harm to the fetus due to pergolide mesylate.

PR-9002-2 T-149308 © 1991, ELI LILLY AND COMPANY

There are, however, no adequate and well-controlled studies in pregnant women. Among women who received pergolide mesylate for endocrine disorders in premarketing studies, there were 33 pregnancies that resulted in healthy babies and four pregnancies that resulted in congenital abnormalities (two major, two minor); a causal relationship has not been established. Because human data are limited and because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers —It is not known whether this drug is excreted in human milk. The pharmacologic action of pergolide mesylate suggests that it may interfere with lactation. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions to pergolide mesylate in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use —Safety and effectiveness in children have not been established.

Adverse Reactions: *Commonly Observed* —In premarketing clinical trials, the most commonly observed adverse events associated with use of pergolide mesylate which were not seen at an equivalent incidence among placebo-treated patients were: nervous system complaints, including dyskinesia, hallucinations, somnolence, insomnia; digestive complaints, including nausea, constipation, diarrhea, dyspepsia; and respiratory system complaints, including rhinitis.

Associated With Discontinuation of Treatment —Twenty-seven percent (27%) of approximately 1,200 patients receiving pergolide mesylate for treatment of Parkinson's disease in premarketing clinical trials in the US and Canada discontinued treatment due to adverse events. The events most commonly causing discontinuation were related to the nervous system (15.5%), primarily hallucinations (7.8%) and confusion (1.8%).

Fatalities —*See* Warnings.

Incidence in Controlled Clinical Trials —The table that follows enumerates adverse events that occurred at a frequency of 1% or more among patients taking pergolide mesylate who participated in the premarketing controlled clinical trials comparing pergolide mesylate with placebo. In a double-blind, controlled study of six months' duration, patients with Parkinson's disease were continued on levodopa/carbidopa and were randomly assigned to receive either pergolide mesylate or placebo as additional therapy.

The prescriber should be aware that these figures cannot be used to predict the incidence of side effects in the course of usual medical practice where patient characteristics and other factors differ from those which prevailed in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other clinical investigations involving different treatments, uses, and investigators. The cited figures, however, do provide the prescribing physician with some basis for estimating the relative contribution of drug and nondrug factors to the side-effect incidence rate in the population studied.

*Events reported by at least 1% of patients receiving pergolide mesylate are included.

Events Observed During the Premarketing Evaluation of Permax —This section reports event frequencies evaluated as of October 1988 for adverse event ocurring in a group of approximately 1,800 patients who took multiple dos pergolide mesylate. The conditions and duration of exposure to pergolid mesylate varied greatly, involving well-controlled studies as well as experienc in open and uncontrolled clinical settings. In the absence of appropriate cor trols in some of the studies, a causal relationship between these events an treatment with pergolide mesylate cannot be determined.

The following enumeration by organ system describes events in terms c their relative frequency of reporting in the data base. Events of major clinica importance are also described in the Warnings and Precautions sections.

The following definitions of frequency are used: frequent adverse events ar defined as those occurring in at least 1/100 patients; infrequent adverse event are those occurring in 1/100 to 1/1,000 patients; rare events are those occu ring in fewer than 1/1,000 patients.

Body as a Whole —*Frequent:* headache, asthenia, accidental injury, abdom inal pain, chest pain, back pain, flu syndrome, neck pain, fever; *Infrequen* facial edema, chills, enlarged abdomen, malaise, neoplasm, hernia, pelvi pain, sepsis, cellulitis, moniliasis, abscess, jaw pain, hypothermia; *Rare:* acut abdominal syndrome, LE syndrome.

Cardiovascular System —*Frequent:* postural hypotension, syncope, hype tension, palpitations, vasodilatations, congestive heart failure; *Infrequen* myocardial infarction, tachycardia, heart arrest, abnormal electrocardiogra angina pectoris, thrombophlebitis, bradycardia, ventricular extrasystole cerebrovascular accident, ventricular tachycardia, cerebral ischemia, atri fibrillation, varicose vein, pulmonary embolus, AV block, shoc *Rare:* vasculitis, pulmonary hypertension, pericarditis, migraine, heart bloc cerebral hemorrhage.

Digestive System —*Frequent:* nausea, vomiting, dyspepsia, diarrhea, co stipation, dry mouth, dysphagia; *Infrequent:* flatulence, abnormal liver functio tests, increased appetite, salivary gland enlargement, thirst, gastroenteriti gastritis, periodontal abscess, intestinal obstruction, nausea and vomitin gingivitis, esophagitis, cholelithiasis, tooth caries, hepatitis, stomach ulce melena, hepatomegaly, hematemesis, eructation; *Rare:* sialadenitis, pepti ulcer, pancreatitis, jaundice, glossitis, fecal incontinence, duodenitis, coliti cholecystitis, aphthous stomatitis, esophageal ulcer.

Endocrine System —*Infrequent:* hypothyroidism, adenoma, diabetes melli tus, ADH inappropriate; *Rare:* endocrine disorder, thyroid adenoma.

Hemic and Lymphatic System —*Frequent:* anemia; *Infrequent:* leukopenia lymphadenopathy, leukocytosis, thrombocytopenia, petechia, megaloblasti anemia, cyanosis; *Rare:* purpura, lymphocytosis, eosinophilia, thrombo cythemia, acute lymphoblastic leukemia, polycythemia, splenomegaly.

Metabolic and Nutritional System —*Frequent:* peripheral edema, weigh loss, weight gain; *Infrequent:* dehydration, hypokalemia, hypoglycemia, iro deficiency anemia, hyperglycemia, gout, hypercholesteremia; *Rare:* elec trolyte imbalance, cachexia, acidosis, hyperuricemia.

Musculoskeletal System —*Frequent:* twitching, myalgia, arthralgia; *Infrequent:* bone pain, tenosynovitis, myositis, bone sarcoma, arthritis; *Rare* osteoporosis, muscle atrophy, osteomyelitis.

Nervous System —*Frequent:* dyskinesia, dizziness, hallucinations, confu sion, somnolence, insomnia, dystonia, paresthesia, depression, anxiety tremor, akinesia, extrapyramidal syndrome, abnormal gait, abnormal dreams incoordination, psychosis, personality disorder, nervousness, choreoatheto sis, amnesia, paranoid reaction, abnormal thinking; *Infrequent:* akathisia, neu ropathy, neuralgia, hypertonia, delusion, convulsion, libido increased euphoria, emotional lability, libido decreased, vertigo, myoclonus, coma, apa thy, paralysis, neurosis, hyperkinesia, ataxia, acute brain syndrome, torticollis meningitis, manic reaction, hypokinesia, hostility, agitation, hypotonia; *Rare* stupor, neuritis, intracranial hypertension, hemiplegia, facial paralysis, brai edema, myelitis, hallucinations and confusion after abrupt discontinuation.

Respiratory System —*Frequent:* rhinitis, dyspnea, pneumonia, pharyngitis cough increased; *Infrequent:* epistaxis, hiccup, sinusitis, bronchitis, voic alteration, hemoptysis, asthma, lung edema, pleural effusion, laryngitis emphysema, apnea, hyperventilation; *Rare:* pneumothorax, lung fibrosis larynx edema, hypoxia, hypoventilation, hemothorax, carcinoma of lung.

Skin and Appendages System —*Frequent:* sweating, rash; *Infrequent:* ski discoloration, pruritus, acne, skin ulcer, alopecia, dry skin, skin carcinoma seborrhea, hirsutism, herpes simplex, eczema, fungal dermatitis, herpe zoster; *Rare:* vesiculobullous rash, subcutaneous nodule, skin nodule, ski benign neoplasm, lichenoid dermatitis.

Special Senses System —*Frequent:* diplopia; *Infrequent:* otitis media, con junctivitis, tinnitus, deafness, taste perversion, ear pain, eye pain, glaucoma eye hemorrhage, photophobia, visual field defect; *Rare:* blindness, cataract retinal detachment, retinal vascular disorder.

Urogenital System —*Frequent:* urinary tract infection, urinary frequency urinary incontinence, hematuria, dysmenorrhea; *Infrequent:* dysuria, breas pain, menorrhagia, impotence, cystitis, urinary retention, abortion, vagina hemorrhage, vaginitis, priapism, kidney calculus, fibrocystic breast, lactation uterine hemorrhage, urolithiasis, salpingitis, pyuria, metrorrhagia, menopause kidney failure, breast carcinoma, cervical carcinoma; *Rare:* amenorrhea, bladder carcinoma, breast engorgement, epididymitis, hypogonadism, leukorrhea nephrosis, pyelonephritis, urethral pain, uricaciduria, withdrawal bleeding.

Glutethimide Treatment of Disabling Action Tremor in Patients With Multiple Sclerosis and Traumatic Brain Injury

Mindy L. Aisen, MD; Mary Holzer, MS, OTR; Michael Rosen, PhD; Mark Dietz, MD; Fletcher McDowell, MD

• Glutethimide has been used to control essential tremor. Its efficacy in the treatment of disabling cerebellar and rubral tremor was assessed in an open study of six patients with multiple sclerosis and two patients with traumatic brain injury. Functional and quantitative tremor severity was assessed before treatment and 7 to 14 days after a stable dose was achieved. Six of eight patients exhibited visible functional benefit from treatment with glutethimide; abstract testing results correlated well with functional status in most cases. Four patients chose to continue to receive medication. Controlled trials of glutethimide to compare its efficacy with that of other medications used in the treatment of action tremor are indicated.

(*Arch Neurol.* 1991;48:513-515)

Glutethimide has been reported to suppress disabling essential tremor.[1] We studied the effects of glutethimide in eight patients with severe cerebellar tremor. Glutethimide is a piperidinedione derivative with sedative-hypnotic and anticholinergic effects. When first introduced, it was widely used as a general tranquilizer, for induction of anesthesia,[2] and as a hypnotic agent. Its popularity waned as concerns about its addictive potential surfaced.[3,4]

PATIENTS AND METHODS

Six patients with multiple sclerosis and two patients with traumatic brain injury were treated with gradually increasing doses of glutethimide (maximum stable doses, 750 to 1250 mg/d); all had disabling action tremor. The condition of seven patients did not respond to other drugs, including propranolol, clonazepam, amitriptyline, and isoniazid. Table 1 summarizes the clinical characteristics and prior therapies of six of the eight patients. Tremor was measured before treatment and 7 to 14 days after a stable dose was achieved. Two types of assessment were employed: functional and abstract.

Functional assessment was performed by a "blinded" occupational therapist. Subjects performed either a timed keyboard test coupled with a hoop test or a set of six function-like tasks derived from a standard clinical rating scale developed by Fahn and colleagues.[5] In the keyboard test, subjects were asked to tap five letter keys in a 1-minute period; the number accurately struck was the score. In the hoop test, subjects had to alternately encircle three 1.3-cm-diameter posts with a 15.2-cm-diameter hoop; the time elapsed to accurately perform the task was recorded. The clinical assessment scale included an estimated amplitude of tremor, handwriting, tracing an Archimedes spiral, pouring water from one cup to another, drinking/eating soup, and a keyboard test. The resulting score ranged from 0 to 32, with 0 reflecting no tremor.

The abstract method consisted of a pursuit-tracking task in which two images appeared on a computer screen. One image, the target, moved around the screen in a seemingly random pattern. The second image moved in response to motion at the end of a customized manipulator with the capacity to move in 3 *df*. The patient's limb was securely placed in a wrist-immobilizing splint affixed to the manipulator; movement in the limb therefore produced movement of the response image on the screen. The patient attempted to make the response image coincident with the target image. After an extended practice period, patients underwent tracking testing for 1-minute intervals. The practice period spanned several days, and data were sampled only after performance plateaued to minimize changes due to learning effects.

DATA ANALYSIS

An IBM-PC-AT–compatible computer (Leading Edge model D2, Leading Edge Corp, Westboro, Mass) with a monochrome screen was used for the tracking display. The display software, developed by Beringhause,[6] provided a seemingly random (repeat time, every 17 minutes) target that moved in the x and y directions at varying frequencies, with a range of 0.08 to 0.5 Hz. Target x and y screen coordinates were written to a hard disk file after each tracking experiment was completed. Data analysis methods developed by Adelstein et al[7,8] were used to derive quantitative measures of tracking fidelity and tremor magnitude. Both were believed to be important, because side effects of treatment (eg, sedation) might impair accuracy despite tremor suppression.

Tremor magnitude or tremor power was quantified by examination of the "residual" portion of the patient's response. The residual portion is that portion of the response signal not linearly related to the target signal. The residual autopower spectrum is calculated by multiplying the autopower spectrum of the response by 1 minus the coherence between the tracking and response signals. Tremor magnitude or tremor power was defined by the area under the residual response spectrum. Tracking fidelity, defined by the signal-to-noise ratio (SNR), was calculated by dividing the area under the target-response cross power density curve by the tremor power. Tremor power assessment provided information about changes in tremor amplitude, and SNR provided infor-

mation about the quality of task performance. Therefore, if tremor suppression was associated with significant impairment due to fatigue or sedation, a decrease in tremor power would be accompanied by a stable or decreased SNR. A decrease in tremor power coupled with a rise in SNR reflected not only tremor reduction but also improved functional performance.

Tremor power and SNR values were generated for x and y dimensions. For the purpose of examining trends before and after glutethimide treatment, x and y values were combined to produce a single SNR and tremor power value for each trial.

RESULTS

Six patients demonstrated functional improvement after glutethimide treatment, one exhibited no change, and one worsened. Table 2 summarizes the results of functional testing.

As shown in Table 3, seven patients were tested by the abstract method: five improved and two worsened. In those who improved, SNR increased 110% to greater than 300%, and tremor power decreased 19% to 96%. An improvement in SNR was always concordant with improvement in tremor power within trials; the degree of improvement frequently varied considerably between these values. This may be due to combined tremor and ataxia in some subjects in whom tremor may be suppressed by medication, producing a decline in tremor power magnitude, but persistent incoordination prevents a proportional rise in SNR. Similarly, sedation may interfere with tracking fidelity even if tremor is suppressed.

Functional improvement correlated somewhat better with a patient's decision to continue therapy than did abstract improvement. Four patients chose to continue to receive treatment, as shown in Table 4. The primary side effect was sedation, and all patients who chose to discontinue glutethimide therapy experienced moderate to profound sedation while receiving the medication.

COMMENT

Six of eight patients exhibited visible functional benefits from treatment with glutethimide. In all but two patients, results of abstract testing correlated well with functional scores. Four of the six patients who exhibited functional improvement chose to continue treatment. All patients who discontinued medication exhibited persistent sedation, in contrast to prior experience with patients with essential tremor, in whom sedative effects rapidly resolved.[1]

Benefit did not relate to underlying diagnosis, as three of six patients with multiple sclerosis and one of two pa-

Table 4.—Testing Summary[*]

Patient	Glutethimide Dose, mg/d	Functional Testing	Abstract Testing	Side Effects	Continued Medication
1	750	I	W	Moderate sedation	Yes
2	750	N	I	Profound sedation	No
3	750	I	I	None	Yes

8	750	W	W	Profound sedation	No

[*] I indicates improved; W, worsened; and N, no change.

tients with traumatic brain injury continued to receive medication, nor did it relate to clinical tremor characteristics. Both patients with traumatic brain injury exhibited rubral tremor, with prominent resting as well as kinetic components, while all patients with multiple sclerosis exhibited primarily action tremor. The patients with traumatic brain injury who responded demonstrated similar improvement in resting and kinetic tremor components.

The neural mechanism of the effect of glutethimide on tremor is unknown. Glutethimide is structurally similar to phenobarbital, sharing its sedative and anticonvulsant effects. It also stimulates substantial anticholinergic activity.[9] Sedative-hypnotic compounds, such as phenobarbital,[10] primidone,[11] and alcohol,[12] have documented abilities to attenuate essential tremor, and anticholinergic drugs are known to reduce resting tremor in Parkinson's disease. Little has been documented about the ability of either anticholinergic or sedative-hypnotic agents to ameliorate tremor due to dysfunction of the cerebellum or its connections. Controlled trials of glutethimide to compare its efficacy with that of other medications used in the treatment of disabling cerebellar and rubral tremor are indicated.

The authors gratefully acknowledge Bruce T. Volpe, MD, Herman Weinreb, MD, and Jackie Friedman, MD, for referral of study patients.

POSTHERPETIC NEURALGIA

There Are Many Words To Describe The Pain.

STABBING
PENETRATING
SHARP
JABBING
SHOOTING
UNBEARABLE
PIERCING
GRIPPING
SEARING

And One For Treating It.

Topical
Zostrix®
(Capsaicin 0.025% w/w) Cream

When patients describe the "hurt" of postherpetic neuralgia (PHN), they use a wide range of words to describe a pain that is often intractable and difficult to treat. Zostrix® (Capsaicin 0.025% w/w) Cream provides an effective topical treatment that alleviates intense pain in most PHN patients.

Topical Zostrix Works Where It Hurts

Zostrix®

(Capsaicin 0.025% w/w) Cream

Topical Analgesic

TARGETED ACTION
Acts on sensory nerves at site of application by selectively depleting substance P, a chemomediator of pain impulses along neuropathways.

EFFECTIVE
Alleviates the intense pain associated with postherpetic neuralgia in most patients. May also benefit patients when added to existing systemic drug regimens.

SAFE
No known interactions with systemic medications commonly prescribed for geriatric patients.

Topical Zostrix Works Where It Hurts

DESCRIPTION

Zostrix Cream contains capsaicin, 0.025% w/w, in an emollient base containing benzyl alcohol, cetyl alcohol, glyceryl monostearate, isopropyl myristate, polyoxyethylene stearate blend, purified water, sorbitol solution and white petrolatum. Capsaicin is a naturally occurring substance derived from plants of the Solanaceae family with the chemical name trans-8-methyl-N-vanillyl-6-nonenamide. Capsaicin is a white crystalline powder with a molecular weight of 305.4. It is practically insoluble in water but very soluble in alcohol, ether and chloroform.

ACTION

Although the precise mechanism of action of capsaicin is not fully understood, current evidence suggests that capsaicin renders skin and joints insensitive to pain by depleting and preventing reaccumulation of substance P in peripheral sensory neurons. Substance P is thought to be the principal chemomediator of pain impulses from the periphery to the central nervous system. In addition, substance P has been shown to be released into joint tissues and activate inflammatory mediators involved with the pathogenesis of rheumatoid arthritis.

INDICATION

Zostrix is indicated for the temporary relief of peripheral neuralgias such as the pain following shingles (herpes zoster). Zostrix is also indicated for the temporary relief of the pain associated with rheumatoid arthritis and osteoarthritis.

WARNINGS

FOR EXTERNAL USE ONLY. Avoid contact with eyes and broken or irritated skin. Do not bandage tightly. If condition worsens, or does not improve after 28 days, discontinue use of this product and consult your physician. **Keep this and all drugs out of the reach of children.** In case of accidental ingestion, seek professional assistance or contact a Poison Control Center immediately.

DIRECTIONS

Adults and children 2 years of age and older: Apply Zostrix to affected area 3 to 4 times daily. Transient burning may occur upon application, but usually disappears in 72 hours. Application schedules of less than 3 to 4 times a day may not provide optimum pain relief and the burning sensation may persist. **Wash hands immediately after applying Zostrix.**

HOW SUPPLIED

1.5 oz tube (NDC 52761-552-45)
3.0 oz tube (NDC 52761-552-85)

Store at room temperature.

Familial Inclusion Body Myositis Among Kurdish-Iranian Jews

Roberto Massa, MD; Boaz Weller, MD; George Karpati, MD; Eric Shoubridge, PhD; Stirling Carpenter, MD

• We report two cases of adult-onset, slowly progressive limb-girdle muscle weakness with a remarkable sparing of quadriceps muscles that developed in patients from different families of Iranian-Kurdish–Jewish origin. Each patient had a similarly affected sibling. The findings by means of muscle biopsies showed abnormalities typical of inclusion body myositis, including abundant lined vacuoles and characteristic cytoplasmic inclusions of 15- to 18-nm filaments. Remarkably, many vacuolated muscle fibers showed immunoreactivity to neural cell adhesion molecule, a fetal muscle antigen. The common origin of these patients from an isolated ethnic group with frequent consanguinity and the familial incidence is indicative of a genetic causation or predisposition, probably with an autosomal recessive inheritance. This familial myopathy is one of several clinical syndromes that share the typical pathological findings of inclusion body myositis. The pathogenic relationship between these different familial forms and the more common sporadic form of inclusion body myositis is not known.

(*Arch Neurol.* 1991;48:519-522)

Inclusion body myositis (IBM) is a distinct variety of idiopathic inflammatory myopathy. The usual features include slowly progressive muscle weakness starting in the sixth or seventh decade of life, male predominance, and resistance to corticosteroid therapy.[1,2] The diagnosis can only be confirmed by the finding of typical cytoplasmic and/or nuclear inclusions in muscle fibers, consisting of 15- to 18-nm filaments.[1] A resemblance of the filaments to paramyxovirus nucleocapsids and their reported immunoreactivity for mumps virus antigens implicated this virus in the causation of IBM,[3,4] but the results of recent studies have not supported this hypothesis.[5,6]

The pathological findings of IBM have also been reported as appearing in younger patients,[1,7-10] and several familial cases with atypical clinical features have been described.[10-14]

We have examined two patients from different families originating from an isolated Jewish population of Iranian Kurdistan, who presented with an adult-onset, slowly progressive myopathy. Each patient reported one similarly affected sibling. Light and electron microscopy of muscle biopsy specimens taken from both patients demonstrated the characteristic findings of IBM. In addition, an immunocytochemical study revealed an expression of neural cell adhesion molecule (nCAM) in most muscle fibers containing lined vacuoles.

REPORT OF CASES

CASE 1.— A 29-year-old woman, the second youngest of 10 children of a Jewish family from Iranian Kurdistan, developed, at the age of 20 years, proximal muscle weakness in the lower limbs, manifesting with difficulty climbing steps and getting up from a squatting position. Onset was gradual, and progression was slow but relentless. During her two pregnancies, there was considerable deterioration of muscle strength. Her examination showed extreme muscle atrophy and weakness of the lower extremity muscles, except the quadriceps that retained a near normal bulk and strength. The most severely affected muscles were the glutei, hip flexors, and hamstrings. In the upper extremities, muscle wasting and weakness were less prominent than in the lower limbs, and predominantly proximal. Neck flexors were moderately weak. There was no weakness of craniobulbar musculature. Tendon reflexes were absent except for weak knee jerks. Sensation was normal. The patient had an increased lumbar lordosis and a waddling gait. Her older brother, 45 years old, had a similar neuromuscular disease, but he was not available for evaluation.

CASE 2.— A 50-year-old woman, the second youngest of seven children of a Jewish family from Iranian Kurdistan, was apparently well until the age of 40 years, when she first noticed instability of gait due to weakness in both lower extremities. Over the years, the leg weakness gradually progressed, and she developed difficulty walking upstairs. About 4 years prior to examination, she noticed weakness of both upper extremities, more marked distally. Examination showed marked atrophy of intrinsic hand muscles. There was asymmetrical weakness in the upper extremities, more marked on the left; it was of moderate degree in the shoulder girdle, slightly more marked in the biceps and triceps, and severe in the forearm and small hand muscles. There was no obvious wasting of lower extremity muscles. There was marked weakness of hip flexors, glutei, hamstrings, and foot dorsiflexors. The strength in the quadriceps and plantar flexors was remarkably preserved. The neck flexors were moderately weak. There was no weakness of craniobulbar musculature. Tendon reflexes were present throughout, but barely elicitable at the ankles. Sensation was normal. She had a markedly waddling and steppage gait. Her only sister, 65 years old, was reported to have a similar neuromuscular disease, but she was not available for examination. The three children (one male and two female) of the proband were examined by us; none of them showed neurological abnormality.

MATERIALS AND METHODS

A biopsy of the biceps brachii muscle was performed in both patients and the biopsy specimens were processed for histochemical, phase, and electron microscopic examination, as previously described.[15] In addition, the expression of immunoreactive class I major histocompatibility complex (MHC I) and nCAM was determined on 4-µm-thick, transverse cryostat sections, by means of the immunoperoxidase technique.[16] An antihuman MHC I monoclonal antibody (PHM4, Cedarlane Laboratories, Hornby, Ontario), at a dilution of 1:50, and an antihuman nCAM monoclonal antibody, undiluted (5.1H11), were used as primary antibodies. doma cells secreting the 5.1H11 antibody (cloned by Dr F. Walsh, Institute of Neurology, Queens Square, London, United Kingdom) were grown in Dulbecco's modified Eagle medium plus hypoxanthine-aminopterin-thymidine medium plus 10% fetal calf serum. The supernatant from pelleted cells was used as the source of the antibody.

RESULTS

Laboratory Examination

Results of laboratory investigations are presented in the Table. Additionally performed immunological tests, including quantitative immunoglobulin levels and erythrocyte sedimentation rate, revealed normal results in both patients.

Muscle Biopsy

Both biopsy specimens demonstrated the characteristic findings of IBM on histochemical, phase, and electron microscopic examination.[1] Histochemical study of cryostat sections revealed many small-caliber muscle fibers, some of which were extremely atrophic (Fig 1). In case 1, there was a tendency for small-caliber fibers to occur in groups. Other fibers were clearly hypertrophic, with a rounded cross-sectional outline. There was a substantial increase in endomysial connective tissue (Fig 1), and in some regions large adipocytes were present between muscle fibers. This was particularly conspicuous in case 2. Centrally situated myonuclei were increased in number. The myonuclei appeared abnormal in many instances: some were enlarged and pale, while others were enlarged and hyperchromatic. Some nuclei contained inclusions (Fig 2, left); some pyknotic nuclear clumps were also present. About one third (case 1) to half (case 2) of the muscle fibers contained vacuolar spaces (Fig 1). Many fibers had multiple spaces, whose size varied from a few micrometers to as much as 30 μm in largest dimension. Some vacuoles were optically empty, but in others there was ill-defined debris along with punctate basophilic granules (Fig 1). Nuclei frequently were present within the vacuolar spaces. Some vacuoles contained impressive eosinophilic inclusions (Fig 2, left and right). There were a few examples of necrosis and phagocytosis of muscle fibers (Fig 3), as well as regener-

Summary of Laboratory Investigations

Test	Patient 1	Patient 2
Serum creatine kinase,* IU/dL	404	159
Electromyography	Polyphasic motor unit potentials, fibrillations	Small, polyphasic motor unit potentials, fibrillations, positive sharp waves
Nerve conduction velocity	Normal	Normal
Brain magnetic resonance imaging	Normal	Not performed
Brain magnetic resonance spectroscopy	Not performed	Normal

*Normal range, 5-140 IU/dL.

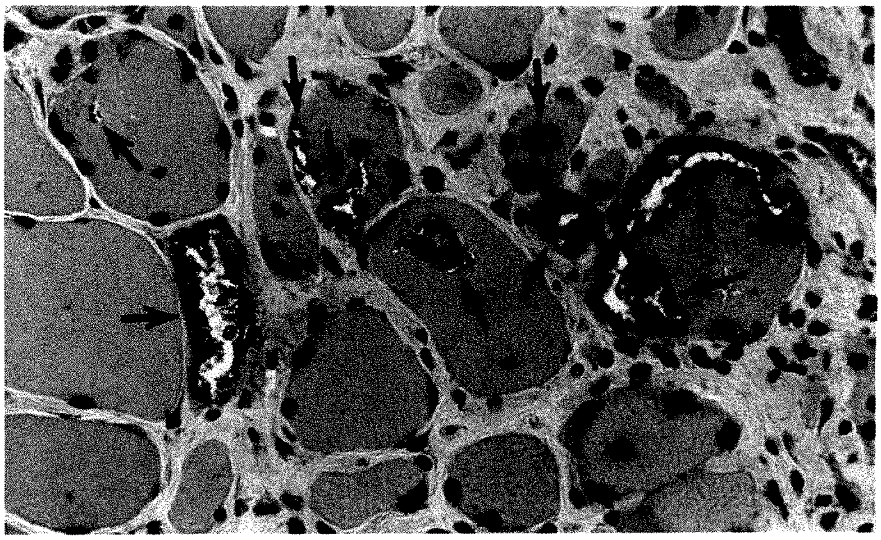

Fig 1.—Patient 2. Several normal-sized or atrophic fibers contain conspicuous small or large lined vacuoles (arrows). There are scattered rounded atrophic fibers, some of which contain central myonuclei. The endomysial connective tissue is markedly increased (hematoxylin-eosin, original magnification ×350).

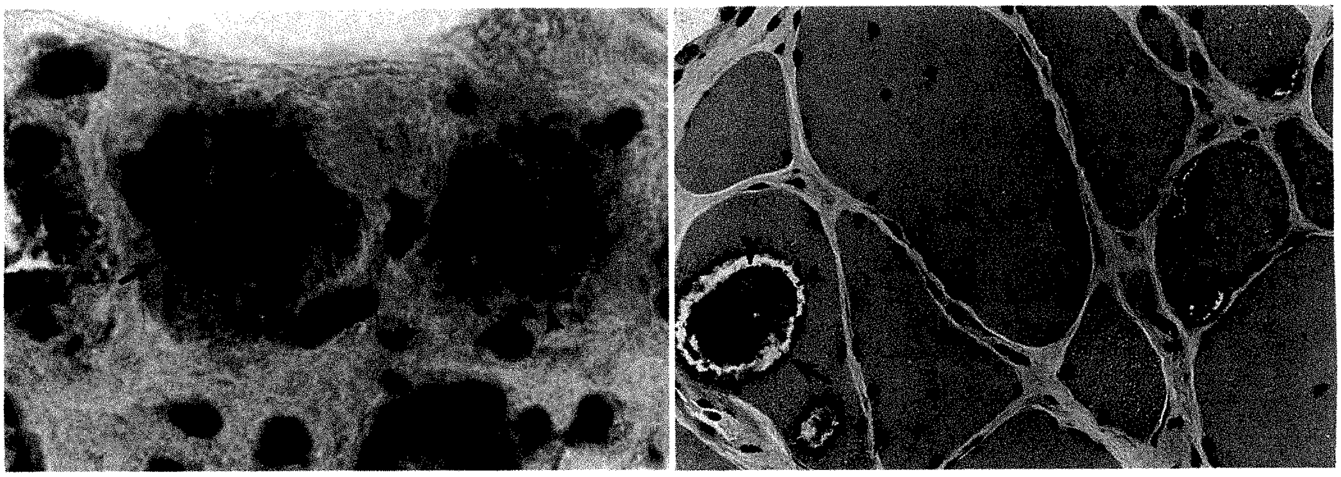
Fig 2.—Left, Patient 2. Large nuclear (arrow) and cytoplasmic (arrowhead) inclusions are present in two very small muscle fibers. The nuclear inclusion causes a marked peripheral crowding of the chromatin. Right, Patient 1. Two conspicuous inclusions (arrowheads) are intermingled with the contents of a large lined vacuole (arrow) (hematoxylin-eosin, original magnification left, ×1400; right, ×350).



ation. A few small mononuclear inflammatory infiltrates were seen between muscle fibers (Fig 3). Both the necrotic fibers undergoing phagocytosis and some scattered regenerating fibers showed moderate to strong expression of MHC I. A few of the fibers containing lined vacuoles were also moderately positive. On the other hand, most of the fibers containing lined vacuoles, although not all of them, showed moderate to strong immunoreactivity for nCAM, either localized to the sarcolemma or, most commonly, evenly distributed throughout the cross-sectional area of the fiber (Fig 4). Regenerating fibers were also nCAM positive. There was no immunoreactive nCAM in vacuole-bearing muscle fibers found in biopsy specimens of four patients with typical, sporadic IBM.

Phase microscopy on resin sections showed that many fibers contained dark granules. In some large fibers, there were foci of Z-disk streaming. Electron microscopy showed membranous whorls and accumulations of characteristic filaments (15 to 18 nm in diameter) in the cytoplasm of several myofibers (Fig 5). Filaments were not found in nuclei in the sections examined.

COMMENT

Our patients presented with a progressive myopathy with onset in the third and fourth decade of life, respectively. The pathological features in both cases were indistinguishable from those of sporadic IBM. Variations in fiber caliber, lined (rimmed) vacuoles, necrotic and regenerating fibers, proliferation of endomysial connective tissue, membranous whorls, and inclusions composed of 15- to 18-nm filaments were found. All these features are characteristic and, in combination, have been considered pathognomonic of IBM.[1,2] The degree of the pathological changes in our patients, especially in patient 2, seemed to be more severe than that in the common sporadic cases of IBM. The pattern of MHC I expression was consistent with that previously described for sporadic IBM.[16] Interestingly, the expression of nCAM was detected by the 5.1H11 antibody in most of the myofibers containing lined vacuoles. Reactivity to this antibody, which is now known to recognize human nCAM,[17] was originally thought to be restricted to human myoblasts, myotubes, and regenerating fibers in diseased adult muscle.[18] However, we have detected a similar reactivity in vacuolated fibers in cases of sporadic IBM, oculopharyngeal muscular dystrophy, and colchicine myopathy, in addition to denervated fibers (manuscript in preparation). In all these instances,

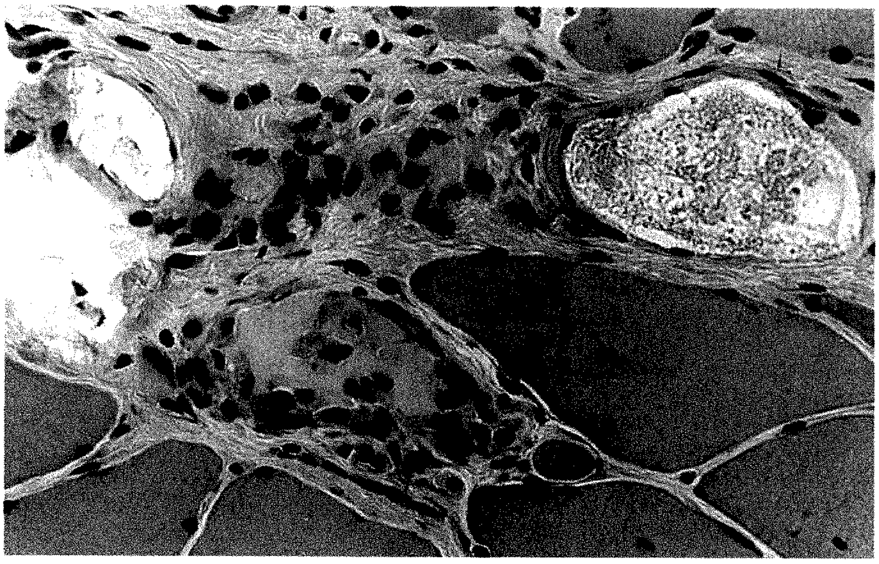


Fig 3.—Patient 1. Mononuclear inflammatory cells are present in the vicinity of a large vein with a necrotic fiber (lower part of the picture) undergoing phagocytosis (hematoxylin-eosin, original magnification ×350).

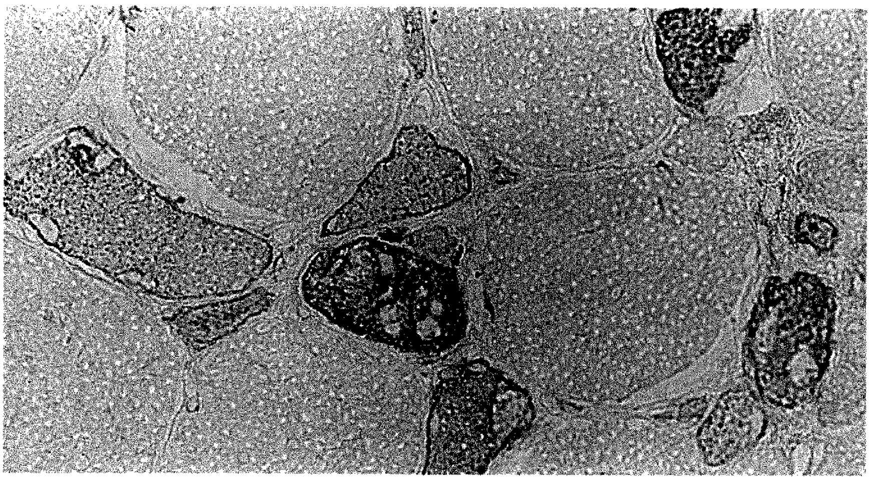

Fig 4.—Patient 1. Several fibers show both diffuse and punctate cytoplasmic, as well as sarcolemmal, immunoreactive neural cell adhesion molecule. The majority of the positive fibers harbor conspicuous lined vacuoles (immunoperoxidase using anti–neural cell adhesion molecule antibody [5.1H11] and biotin-streptavidin display systems, original magnification ×350).

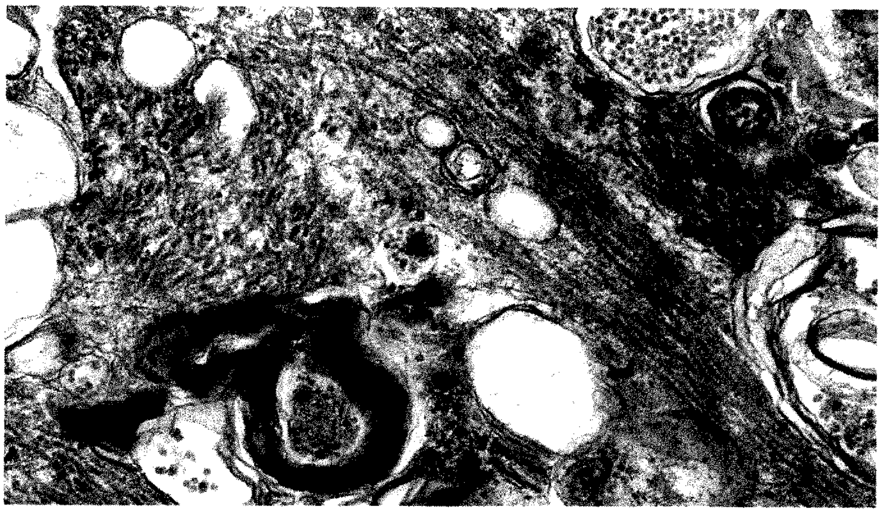
Fig 5.—Patient 2. Electron micrograph shows abnormal 15- to 18-nm filaments characteristic of inclusion body myositis surrounded by small membranous whorls (original magnification ×40 000).



myofibers might undergo a process of dedifferentiation, leading to reexpression of fetal antigens such as nCAM.

The clinical picture observed in these patients is also consistent with the usual presentation of IBM, with two exceptions: one is the relatively early onset, and the other is a striking sparing of quadriceps muscles. Inclusion body myositis most often begins in the sixth or seventh decade of life, although some cases have been described beginning as early as the second decade.[7-10] The remarkable sparing of quadriceps muscles, even when all other muscles in the lower extremities show practically complete paralysis (as was the case in patient 1), makes this syndrome phenotypically distinct.

Both our patients reported one sibling having similar symptoms. These persons were not available for clinical examination, but the description of their symptoms is consistent with progressive weakness of proximal limb muscles. This suggests a familial incidence of IBM in these cases.

Although there is no direct evidence of consanguinity within or between these two families, they have a common origin in a small and isolated Jewish population in Iranian Kurdistan, with a high frequency of intermarriages. The familial incidence and the geographic segregation are indicative of a genetic causation or predisposition, probably inherited as an autosomal recessive trait. The reported absence of weakness in the parents of the patients and the absence of clinical findings in the children of patient 2 are consistent with this suggestion. However, a future onset of the disease in the latest generation cannot be completely ruled out at this point.

A number of articles have described the presence of rimmed vacuoles and the typical cytoplasmic or nuclear filaments in patients with undefined familial myopathies. Matsubara and Tanabe[11] reported these pathological findings in two siblings with an autosomal recessive, progressive distal myopathy developing during the third decade of life. Eisen et al[10] described a progressive distal myopathy with onset in early childhood in a man whose muscle biopsy specimen revealed the typical findings of IBM. His brother was affected with a similar illness, but he was not studied. Fukuhara et al[12] reported a "variant form of oculopharyngeal muscular dystrophy" in a man with onset in the third decade of life. His son developed a distal myopathy during infancy. Examination of muscle biopsy specimens taken from these patients showed rimmed vacuoles. Electron microscopic findings in the son demonstrated cytoplasmic inclusions consisting of 13- to 19-nm filaments. Cole et al[13] investigated a family in which five of six male siblings were affected by a progressive myopathy beginning in early childhood. Examination of muscle biopsy specimens obtained from all patients revealed the characteristic findings of IBM. Four of these patients presented an additional feature, ie, a markedly abnormal appearance of cerebral white matter on computed tomographic scan and magnetic resonance imaging of the brain. There was no clinical or other laboratory evidence of a white matter dysfunction. Sunohara et al[14] described five Japanese patients from three families, presenting a progressive distal myopathy with onset in early adulthood. Pathological findings included rimmed vacuoles and, in some cases, typical intranuclear filaments. The disease was probably inherited as an autosomal recessive trait.

The patients whom we describe here share the same pathological findings with the other reported examples of familial IBM. On the other hand, their clinical presentation included neither oculopharyngeal involvement nor a predominantly distal weakness. In addition, there was no evidence of white matter abnormality by means of magnetic resonance imaging or spectroscopy, respectively, in our two patients. For these reasons, we suggest that our patients represent a distinct form of familial IBM peculiar to their ethnic group.

Although no previous familial cases of IBM in Iranian Kurdish Jews have, to our knowledge, been reported, we found that a "rimmed vacuole myopathy" in Iranian Jews was described by Argov and Yarom.[19] They investigated the condition of nine patients from four families, with a progressive generalized myopathy sparing the quadriceps that had begun in the third or fourth decade of their life. These authors also emphasized the conspicuous sparing of quadriceps muscles. Muscle biopsy specimens were characterized by the presence of rimmed vacuoles. Abnormal filaments were not mentioned in the description of the two cases processed for electron microscopic examination. Inheritance was believed to be autosomal recessive. Our cases share many features with the above-mentioned ones, such as Iranian-Jewish origin; probable autosomal recessive inheritance; age at onset of disease; distribution of weakness, including the notable preservation of quadriceps; and the light microscopic findings. We believe, therefore, that our patients and those described by Argov and Yarom[19] represent the same entity.

This familial myopathy is a further indication that several clinical syndromes share the typical pathological findings of IBM. The understanding of the pathogenetic mechanism(s) at the molecular level will clarify the relationship between the sporadic form and the present and other familial forms of IBM.

Altered Cutaneous Sensation in Trigeminal Neuralgia

Turo J. Nurmikko, MD

• Noninvasive quantitative somatosensory tests were used to measure sensory perception thresholds on the faces of 26 patients with idiopathic trigeminal neuralgia. The affected divisions were determined by the presence of trigger zones. Elevations of thresholds of sensations subserved by both large- and small-diameter fibers were found both in the affected and in the unaffected adjacent divisions when compared with the healthy side. The findings are interpreted as further evidence of combined peripheral and central pathologic conditions in idiopathic trigeminal neuralgia.

(*Arch Neurol.* 1991;48:523-527)

The diagnosis of tic douloureux, or idiopathic trigeminal neuralgia (ITN), is based on the history of mechanically elicited pain paroxysms and the absence of neurological deficits on routine examination.[1-3] Any sensory abnormality observed by the clinician is considered to prompt careful neuroradiological and laboratory evaluation to exclude treatable causes for the condition, such as local tumors, vascular malformations, infections, and multiple sclerosis plaques.[2,4,5] Yet many authors refer to occasional sensory findings in patients with ITN, although no systematic data are presented.[4,6-9] There is also some evidence of electrophysiological abnormalities in this condition,[10,11] although conflicting results have also been reported, even from the same laboratory.[12-14] Histopathological changes as well as completely normal results have been described at various levels of the trigeminal pathway,[15-17] and since it is not clear whether the findings represent genuine or postmortem changes, caution in interpretation is recommended.[2]

While the etiopathogenesis of ITN remains largely unresolved, evidence has been accumulating from animal and human studies making it difficult to explain the characteristics of this capricious pain condition without considering both central and peripheral factors.[9,18-20] Pain paroxysms set off by innocuous stimuli within the trigger zones and outlasting the duration of the stimulus,[9,18] radiation of pain outside the involved territory,[18] and efficacy of drugs capable of facilitating segmental or afferent inhibition in the trigeminal nuclei[19] are best explained by central pathophysiology. On the other hand, observations of compression, distortion, or stretching of the trigeminal nerve[7,21] as well as relief provided by various procedures affecting the nerve practically anywhere along its course[3,22,23] stress the significance of the peripheral input. Why does facial sensation in ITN escape the slightest impairment despite an obvious trigeminal pathway dysfunction, as generally assumed?

The aim of the present study was to ascertain whether, in fact, sensory abnormalities can be found in ITN by using systematic and quantitated somatosensory measurements and, if so, whether they elucidate the pathogenetic mechanisms in this condition. Sensory thresholds in the affected divisions and outside the affected divisions on the painful side of the face were measured and compared with those of the contralateral homologous sites in a group of patients suffering from ITN. Because of the well-known problem of correctly assessing the exact situation and distribution of the pain,[2] an approach of searching for cutaneous and mucosal trigger zones and naming the affected division accordingly was chosen. The results presented here are suggestive of changes in the trigeminal somatosensory system, found not only in the affected but in the adjacent nonsymptomatic divisions as well.

PATIENTS AND METHODS

Patients

Twenty-six patients with a history of ITN (tic douloureux) and one or several clinically verifiable trigger zones within the trigeminal nerve distribution participated in the study. The ITN was diagnosed after the patient presented a history of pain with the following characteristics: (1) electric, shock-like, stabbing pains; (2) pain of abrupt onset and abrupt termination; (3) painfree intervals between attacks; (4) unilateral pain during an attack and restricted to a zone innervated by the trigeminal nerve; and (5) attacks triggered by local nonnoxious stimulation.[3,20] In 17 patients, pain occurred on the right side and in nine patients on the left side. The mean age was 65.8 years (range, 47 to 81 years); female-to-male ratio, 22:4; and mean duration of ITN, 58.6 months (range, 2 to 180 months). No patient had undergone neurosurgical operations or received nerve blocks. All but two patients were receiving a carbamazepine during the tests with dosage ranging from 200 to 1200 mg daily; three patients used baclofen in addition. Accord-

Reprint requests to the Department of Neurology, University Central Hospital, 33520 Tampere, Finland (Dr Nurmikko).

ing to recent recommendations,[20] no routine radiological investigations were carried out, but any suspicion of a neurological disease raised by the sensory findings of the ongoing study prompted a computed tomographic evaluation with special attention to the basal structures of the brain. A computed tomographic scan of the brain was judged necessary in 15 patients and turned out normal in each case. Nineteen patients eventually had surgery (radiofrequency or glycerol gangliolysis, 17 patients; microvascular decompression, two patients). The final diagnosis of ITN was agreed on by at least two specialists (a neurologist and a neurosurgeon).

Excluded from the study were those patients with a history of head trauma, mental disease, alcohol or drug abuse, severe systemic or metabolic disease, and any major neurological disease. None of the patients had a history suggestive of incipient dementia. All patients gave informed consent.

Trigger zones were systematically assessed and localized as accurately as possible. This was done by gently tapping the skin of the face or the intraoral mucosa with a small glass rod. Because almost all patients were taking medication, actual tics developing into fullblown trigeminal attacks were not anticipated. To qualify for a trigger zone, a spot on the skin or mucosa had to be recognized, by the patient, as frankly painful on touching and a shooting sensation away from it had to be present. In this fashion, definite trigger zones were elicited in 28 divisions in 26 patients. They were found only in the second and third division. Some patients gave a history of pain paroxysms extending outside the trigger zones as reported before.[18,24] Some patients reported migration of trigger zones over the years.[9] Summary of clinical data is presented in Table 1.

*ITN indicates idiopathic trigeminal neuralgia; V1, ophthalmic division; V2, maxillary division; V3, mandibular division; C, carbamazepine; B, baclofen; Nil, no medication.

Methods

Measurements were carried out in quiet laboratory conditions, after a careful explanation of used methods. All six trigeminal divisions (ophthalmic [V1], maxillary [V2], and mandibular [V3], bilaterally) were tested in randomized order. In order not to accidentally cross the boundaries between two adjoining dermatomes, the measuring sites were restricted to those shown by the shaded areas in the Figure. If a pain paroxysm was inadvertently evoked by trigger zone exploration, then a period of 30 minutes was allowed to pass before resuming the test.

Warm, cold, hot pain, and cold pain thresholds were measured with the Thermotest (Somedic AB, Stockholm, Sweden) using a modification of the Marstock technique.[25,26] A Peltier-type thermode 3.6 cm^2 in size was warmed up or cooled down at a rate of 0.5°C to 1.5°C per second. Measurements started from an adapting temperature of 30°C. The patients responded to each individual thermal sensation by pressing a switch that reversed the direction of temperature change and allowed the thermode to return to the baseline temperature. Each measurement was done three to five times, and the average was calculated. Cold pain was measured once; a cutoff point was determined at 5°C. The results were expressed in degrees centigrade.

Tactile sensation was measured with von Frey filaments of equal length and varying diameters (Pressure Aesthesiometer, Stoelting Co, Chicago, Ill), which were applied in descending and ascending order of magnitude to assess both the disappearance and appearance thresholds (at least five applications per filament). Care was taken to avoid stroking the skin with the hair and to only do an indentation. The force required to bend each filament (in grams) was converted to log units.

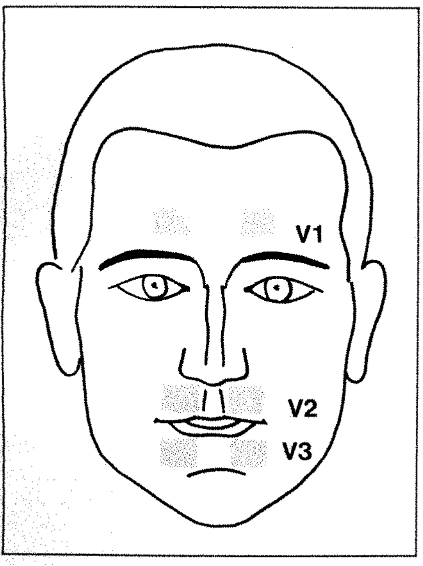
Pinprick sensation was tested with weighted needles.[26] The needles (25-mm, 24-gauge needles weighing from 0.2 to 5.2 g) were on the plungers of 5-mL plastic syringes moving freely. By holding the syringe, the examiner could guide the needle of any weight perpendicularly to the area tested; in essence, it was only the weight of the needle that determined the force and subsequent pinprick sensation. The patient reclined and was verbally cued before each stimulus to ensure attention. Similarly to tactile stimulation, this test was carried out in a descending and ascending manner, each application repeated at least five times. The results were expressed in milligrams.

Two-point discrimination was measured with a Weber's compass, moving the instrument gently on the tested skin area to improve sensitivity.[27] Three ascending and descending series in increments of 1 to 2 mm were administered in alternating order. The results were expressed in millimeters.

Temperature was measured in each division, after acclimatization in a draft-free room for 20 minutes, by means of free thermocouples attached to the skin (Digitron Instruments, model 4071, Hertford, United Kingdom) and expressed in degrees centigrade.

For each somatosensory threshold, comparisons were made between the painful side and the contralateral side. Results from measurements were pooled to form two pairs representing different measurement sites as follows: (1*a*) affected divisions characterized by the presence of trigger zones (TRI-IPS), (1*b*) contralateral mirror-image divisions (TRI-MIR), (2*a*) unaffected, trigger-free divisions ipsilateral to 1*a* (ADJ-IPS), and (2*b*) contralateral mirror-image divisions (ADJ-MIR). By the definition adopted for this study, in a patient with a trigger zone confined to the V3 division, the adjacent division automatically was the maxillary (V2) division. In a patient with trigger zones confined to the V2 division, both ophthalmic (V1) and mandibular (V3) divisions were designated as adjacent. In a patient with trigger zones found in both V2 and V3 divisions, the adjacent division, of course, was the ophthalmic division. In this fashion, 28 affected divisions and 44 adjacent divisions were arrived at.

In both sets of comparison, significances between differences of means of perception thresholds in the corresponding divisions



Sites chosen for measuring the somatosensory perception thresholds. The trigeminal divisions are as follows: V1, ophthalmic; V2, maxillary; and V3, mandibular.

Table 2.—Somatosensory Perception Thresholds in Patients With Idiopathic Trigeminal Neuralgia: Affected Divisions*

	Divisions		
Threshold	**TRI-IPS**	**TRI-MIR**	P†
Warm, °C	33.9 (0.3)	33.1 (0.2)	<.0005
Cold, °C	28.7 (0.2)	28.7 (0.2)	NS
Hot pain, °C	42.4 (0.7)	42.2 (0.7)	NS
Cold pain, °C	9.9 (1.3)	9.0 (1.1)	NS
Pinprick, mg	584 (120)	410 (52)	NS
Touch, log$_{10}$0.1 mg	2.43 (0.11)	2.13 (0.09)	<.002
2-point discrimination, mm	10.5 (0.9)	10.4 (0.8)	NS

*TRI-IPS indicates affected division with trigger zones; TRI-MIR, contralateral mirror-image division; and NS, not significant. All values are the mean (SEM).

†P values given in levels of significance for differences between the symptomatic and the contralateral side (Student's *t* test for paired samples, two tailed). To compensate for multiple comparisons, the significance level was set at $P < .007$.[28]

Table 3.—Somatosensory Perception Thresholds in Patients With Idiopathic Trigeminal Neuralgia: Adjacent Divisions*

	Divisions		
Threshold	**ADJ-IPS**	**ADJ-MIR**	P†
Warm, °C	33.9 (0.3)	33.3 (0.2)	<.005
Cold, °C	28.6 (0.2)	28.7 (0.2)	NS
Hot pain, °C	43.7 (0.5)	43.2 (0.5)	<.005
Cold pain, °C	9.3 (1.0)	9.8 (0.9)	NS
Pinprick, mg	562 (85)	446 (82)	NS
Touch, log$_{10}$ 0.1 mg	2.35 (0.07)	2.23 (0.07)	.015 (NS)
2-point discrimination, mm	10.9 (0.7)	9.6 (0.6)	<.0005

*ADJ-IPS indicates adjacent trigger zone free division, ipsilateral to TRI-IPS; ADJ-MIR, mirror-image division; and NS, not significant. All values are the mean (SEM).

†P values given in levels of significance for differences between the symptomatic and the contralateral side (Student's *t* test for paired samples, two tailed). To compensate for multiple comparisons, the significance level was set at $P < .007$.[28]

were analyzed using Student's two-tailed *t* test for paired samples. Due to multiple comparisons, a Bonferroni correction procedure to adjust the significance level was employed. The correction was obtained by dividing the alpha level by the total number of comparisons in each set. For seven pairwise a priori comparisons, the significance level was scaled down to $P < .05/7 = 0.007$.[28]

RESULTS

In the affected divisions (TRI-IPS), elevated warm and tactile thresholds were observed when compared with those in the mirror-image divisions (TRI-MIR). In the adjacent (ADJ-IPS) divisions, comparison with the contralateral divisions (ADJ-MIR) revealed significant elevations of warm, hot pain, and two-point discrimination thresholds, while a change of tactile threshold demonstrated an apparent trend for significance. The results are summarized in Tables 2 and 3.

Because medication may have an effect on perception, direct comparisons of the individual somatosensory thresholds with the available normative data were considered inappropriate. It seemed reasonable, however, to assume that medication would not significantly interfere with the degree of sensory asymmetry between the two sides of the face. From a group of healthy subjects of comparable age and sex distribution (n = 20; mean age [SD], 68.5 [9.2] years; female-to-male ratio, 12:8) who underwent the same tests in all six trigeminal divisions, mean asymmetry indexes (defined as the ratio between right and left sides) and standard deviations were calculated for each level. Any sensory function measured in the patient with ITN was defined as abnormal if the degree of asymmetry, ie, measured values between the affected and the contralateral side, exceeded the control group mean by at least 3 SDs. Abnormalities of thermal thresholds were found in eight patients, tactile thresholds in eight, pinprick thresholds in four, and two-point discrimination in three patients. When the results were combined, 15 of 26 patients showed at least one abnormal measure of sensation, mainly a threshold elevation in TRI-IPS or ADJ-IPS divisions, or both. In only one patient was there an abnormally low threshold (for hot pain in the TRI-IPS division).

There were no temperature asymmetries (TRI-IPS of 31.0 ± 0.4°C vs TRI-MIR 30.9 ± 0.4°C, not significant; and ADJ-IPS of 31.2 ± 0.2°C vs ADJ-MIR of 31.2 ± 0.2°C, not significant).

Immediately after gangliolysis, trigger zones were completely abolished and all thresholds were elevated in the treated divisions. No systematic changes were found after the two microvascular decompressions. The results were not subjected to statistical analysis because of the small number of patients tested.

COMMENT

On routine examination, when crude sensory tests are employed, observations of hypalgesia and hypesthesia are infrequent in ITN.[3,20] When more sophisticated and quantitated methods are used, small-scale sensory abnormalities may become apparent. In this study, raised thresholds were found both in the affected divisions and the nonsymptomatic contiguous divisions, indicating involvement of the nearby "silent" branch, too. Sensory functions subserved by both large- and small-diameter fibers were affected. The numerous reports of trigeminal root indentation or distortion by a vascular loop or similar structure, witnessed at operation,[5,7,21] provide a reasonable explanation for these findings. Whether they bear any causal relationship to ITN will be discussed below.

According to the study design, each patient served as his/her own control. The importance of using the patient's healthy side for comparison is underscored by two recent studies by Leandri and coworkers assessing somatosensory evoked potentials in ITN.[11,12] When early scalp responses evoked by the stimulation of both infraorbital nerves were compared between sides, delays of conduction were found on the painful side in nine of 38 cases.[11] When the authors performed only unilateral recordings, they could not detect significant deviations from normal values.[12]

One might dismiss the results of the present study as coincidental and due to patient expectation or the masking effect of trigeminal pain. In light of the used techniques, this seems highly unlikely. The patients were tested when at least 30 minutes from the last attack had elapsed. Thermal stimuli never caused pain paroxysms in the patients; yet just these thresholds were quite often abnormal. Threshold alterations were also more frequently present in the nonsymptomatic adjacent divisions where testing is not likely to be negatively affected by poor patient cooperation. The interpretation of results is not hampered by overlapping of dermatomes, either; there is very little functional overlap between the three trigeminal dermatomes.[29] The results are best explained by a lesion somewhere along the trigeminal afferent pathway, probably in the presynaptic part,[11] affecting not only those fibers innervating the painful division but the adjacent division as well. The discrepancy among the locations of pain, trigger zones, and sensory deficits does not confound the issue. In fact, it may offer an additional clue to the pathogenesis of ITN.

In a recent study,[26] Nurmikko and Bowsher reported on 12 patients with ophthalmic postherpetic neuralgia, half of whom suffered from severe touch-evoked pain (mechanical allodynia) in the maxillary division. Two aspects of this finding were discussed: expansion of the sensory dysfunction outside the originally affected division and pain caused by activation of nonnociceptive low-threshold mechanoreceptors. The authors concluded that their observations were clinical examples of the alterations in the central nervous system physiological mechanisms, known to take place in animals, after peripheral nerve unjury.[30] Deafferentation results in second-order neurons beginning to respond to stimuli from other than the usual anatomic areas. The expansion of the receptive fields is likely to include changes in the domain of sensory quality, too, so that neurons formerly responding to noxious stimuli start responding to other stimuli, such as tactile.[31] The resemblance between postherpetic neuralgia and ITN in this respect is evident. In each condition, there is evidence of mechanical allodynia (presenting as trigger zones in ITN) and a more widespread sensory dysfunction than the patient's pain description suggests. Although there are qualitative and quantitative differences, they may simply reflect the difference in the degree of peripheral nerve injury, which in ITN is minor and in postherpetic neuralgia is major. Perhaps the sensory abnormalities in ITN represent the primary lesion to the nerve or root. The trigger zones and pain paroxysms might then reflect various central alterations in the brain-stem trigeminal complex, as suggested previously.[9,19]

Some patients with ITN have a history of ipsilateral nonparoxysmal trigeminal pain weeks, months, or years before classic pain paroxysms develop.[32] Mitchell[33] noted that the typical ITN pains often spread to involve an adjacent division of the trigeminal nerve. Pretrigeminal neuralgia may, therefore, represent the first clinical manifestation of the neuropathic process that slowly, in a selected group of patients, leads to ITN. Accurate neurophysiological measurements at this early stage of the condition might elucidate the nature of the involvement of the trigeminal afferent pathways before the genesis of tic pain.

The findings of the present study are interpreted as further support for the hypothesis of combined peripheral and central pathophysiological mechanisms operant in ITN.[9,19,20] A lesion in the trigeminal nerve or root will result not only in sensory loss but also in functional changes of the receptive fields of the second-order neurons in the brain-stem trigeminal complex. As pointed out by Fromm and coworkers,[19] there is also pharmacological evidence of a failure of segmental inhibition in the trigeminal nucleus. The trigger zones (and pain paroxysms) presumably reflect these central alterations rather than the peripheral injury.

The reason for the predilection of the second and third divisions in the fully developed syndrome is obscure.[18,24] Some authors have attempted to account for it by drawing attention to the anatomy of the trigeminal nerve. Kerr[1] has proposed a permanent pulsatile contact of the carotid artery with the ventral surface of the gasserian ganglion, where mainly the second and third divisions are likely to be involved, because the first division is located farthest from the artery.[1] Jannetta[7] has reported compression of the superomedial aspect of the nerve root by the superior cerebellar artery in patients with pain in the second and third divisions, while the anteroinferior cerebellar artery seems to compress the inferior surface of the root in first division neuralgia cases.[7] According to the present study, however, no such accurate anatomical relationships are required to explain the locations of trigger zones and pain. Migration of trigger zones, mentioned by several authors before[1,4,5] and meticulously mapped by Dubner et al[9] in one patient with ITN, as well as the known tendency of the tic pain to disappear for long periods[2,4,20] militate against such a theory of simple local compression. A recent critical review of the subject also questions the significance of the microvascular decompression at the root level.[5] While the findings reported here add to the evidence of trigeminal pathway irritation or lesion (from any cause), some other unknown factor(s) leading to the development of ITN with its characteristic features must be inferred. The reason for the concentration of trigger zones in the central mask of the face cannot be explained adequately with available data, but is likely to lie in the complex interconnections of the neurons of the trigeminal nuclei, or even more rostrally.

This study was supported, in part, by a grant from the Tampere (Finland) Brain Research Center.

I am indebted to the patients who kindly participated in the study and David Bowsher, MA, MD, PhD, MRCPEd, MRCPath; Chris Wells, MB, ChB, LMCC, FFARCS; and John Miles, MB, ChB, FRCS, who referred some of the patients.

Neurophysiologic Studies of the Peripheral Nervous System in Nephropathic Cystinosis

Michael R. Swenson, MD; Steve Rimmer, MD; Jerry A. Schneider, MD; Ronald B. Melles, MD; Doris A. Trauner, MD; Barrett Katz, MD

• Cystinosis is an autosomal recessive metabolic disorder in which nonprotein cystine accumulates within most body tissues due to a defect in lysosomal cystine transport. Neurologic declarations are only recently being recognized. We studied 13 cystinotic subjects (aged 5 to 21 years old), determining median motor and sensory nerve conduction velocities, F waves, peroneal motor nerve conduction velocities, sural sensory nerve conduction velocities, median sympathetic skin response, electrocardiogram R-to-R variability, and blink reflex analysis. The results were normal. We conclude that neurophysiologic testing suggests relative sparing of the peripheral nervous system in nephropathic cystinosis.

(*Arch Neurol.* 1991;48:528-529)

Cystinosis is an autosomal recessive metabolic disorder in which nonprotein cystine accumulates within most body tissues.[1] The cystine accumulates within the lysosomes of cells due to a defect in lysosomal cystine transport.[2] Cystinosis can be divided into two major clinical groups, nephropathic and benign. Nephropathic cystinosis can be further divided into infantile and late-onset (juvenile or adolescent) forms. The infantile form is the most common, and the most devastating. Systemic complications include renal Fanconi syndrome with rickets, growth retardation, and renal failure that necessitates renal transplantation by an average age of 10 years. Children with infantile cystinosis are now surviving to the second and third decade of life, permitting evaluation of the long-term effects of cystinosis on nonrenal tissues. While patients with cystinosis had been believed to have normal neurologic function, recent evidence suggests that there may be central nervous system involvement. Neurologic abnormalities that have been described include confusion and short-term memory loss, rigidity, myopathy, tremor, gait apraxia, generalized hypotonia, intention tremor, mild diffuse hyperreflexia, speech difficulties, slowed saccades, decreased corneal sensitivity, abnormal visual contrast sensitivity, and enhancement of the photic-induced sneeze reflex.[3-13] We performed studies of the peripheral nervous system in patients with nephropathic cystinosis to determine if the pathophysiologic mechanisms that result in central nervous system dysfunction also affect the peripheral nervous system.

PATIENTS AND METHODS

We studied 13 patients with nephropathic cystinosis (aged 5 to 21 years old; 10 patients were male). All patients were examined neurologically. Ten of the 13 had poor gross and/or fine motor skills for their age. Seven of the 13 exhibited generalized hypotonia in the face of normal or brisk deep tendon reflexes. Five of the 13 were borderline or frankly microcephalic. None showed evidence of peripheral neuropathy or neuromuscular dysfunction. No patient had any other systemic disease known to affect the neuromuscular system. Eleven patients had been receiving long-term oral cysteamine therapy. One patient had been taking cysteamine intermittently, and one patient had never received cysteamine therapy. Only the latter two patients had undergone renal transplantation.

For median motor nerve conduction velocities, an active electrode was placed over the thenar motor point with a reference distally on digit 1 and ground on the dorsal hand. The median nerve was stimulated at the wrist and elbow. Amplitude was measured from baseline to electronegative peak, and distal latency from shock artifact to onset of the electronegative potential. Distance was measured with a flexible cloth tape. F waves were elicited by stimulation of the median nerve at the wrist with anode distal to cathode. The shortest onset latency of eight F waves was recorded.

Peroneal motor nerve conduction velocities were determined with an active electrode over the center of the extensor digitorum brevis, and the reference electrode on digit 5; ground was over the dorsal aspect of the foot. Stimulation was applied at the ankle and at the fibular neck. Amplitudes, latencies, conduction velocities, and F waves were calculated as above. F waves were measured as the shortest onset of eight responses from the ankle.

Sural sensory nerve conduction velocities were recorded from a block electrode behind the lateral maleolus, and stimulation of the sural nerve was recorded 14 cm proximally. The best of four responses was taken; signal averaging was employed when necessary with eight to 16 sweeps. Latencies to electronegative onset and peak were determined. Amplitudes were measured from baseline to electronegative peak. Limb skin temperature was controlled at 34°C with an automatic feedback thermistor controlled heat lamp (Dantec Model 15H02). One-centimeter tin disk electrodes were used throughout.

Median sympathetic skin responses were determined by placing an active electrode on the palm, reference, and ground on the dorsum of the hand. Responses were recorded after stimulation of the median nerve at the wrist, ipsilaterally. Median sympathetic skin response amplitude and latency to onset were measured.

R-R variability was determined by record-

ing the electrocardiogram. The R-R range of 10 cycles was determined during normal tidal respiration, and again during one deep inspiration with Valsalva maneuver. The ratio of these two ranges was recorded. Two trials were taken from each subject, in the recumbent position.

Blink reflexes were recorded in four subjects. The active electrode was placed at the inferior orbital rim below the outer canthus. Stimulation at the supraorbital notch was achieved with a constant current stimulator. R1 and R2 responses, both ipsilateral and contralateral, were recorded after 10 trials at each site.

RESULTS

In all subjects, peripheral nerve conduction velocities and compound motor action potentials fell within the normal range for age (Table 1). The electrocardiogram R-to-R variability in 11 cystinotic subjects was normal. Blink reflexes could only be obtained in four subjects; all showed normal latencies (Table 2).

Table 1.—Peripheral Nerve Conduction Studies in Nephropathic Cystinosis*

Study	n	Mean (SD)	Range
Median motor amplitude, mV	11	6.5 (2.57)	2.8-11.5
Median motor distal latency, msec	11	2.6 (0.42)	1.9-3.5
Median motor conduction velocity, m/sec	11	54.5 (2.80)	50.0-58.6
Median motor F response, msec	8	19.5 (1.77)	17.0-22.0
Peroneal motor amplitude, mV	12	3.9 (2.68)	0.5-8.5
Peroneal motor conduction velocity, m/sec	12	53.5 (5.09)	46.3-65.5
Peroneal motor F response, msec	5	27.4 (5.94)	19.0-35.0
Sural sensory amplitude, μV	12	17.0 (5.22)	8.0-26.0
Sural sensory conduction velocity, m/sec	12	53.3 (5.22)	46.7-63.6
MSSR, mV	11	0.6 (0.48)	0.1-1.6
MSSR latency onset, msec	11	1.5 (0.28)	1.0-2.0

*MSSR indicates median sympathetic skin response.

Table 2.—Blink Reflex Latencies in Nephropathic Cystinosis*

Side Stimulated	Wave	n	Mean (SD)	Range
Right	R1	4	10.5 (0.71)	10.0-11.5
Right	R2 ipsilateral	4	29.3 (7.37)	22.0-37.0
Right	R2 contralateral	4	30.0 (6.27)	22.0-35.0
Left	R1	3	10.8 (0.29)	10.5-11.0
Left	R2 ipsilateral	4	28.4 (7.25)	21.0-36.0
Left	R2 contralateral	3	30.3 (8.08)	21.0-35.0

*The blink reflex latencies are given in milliseconds.

COMMENT

Autopsy studies have shown central nervous system pathologic findings in patients with cystinosis. There may be high parenchymal levels of cystine,[3,10] accumulations of cystine crystals within the choroid plexus, pineal gland, and meninges,[10] and extensive demyelination of the internal capsule and brachium pontis.[11] Results of previously reported electromyography demonstrate low amplitude, polyphasic motor-unit potentials of brief duration.[12] Muscle biopsy specimens have demonstrated variations in fiber size, atrophy of type I fibers, and numerous ring fibers, suggesting an underlying myopathy.[12] A recent report of neurologic complications in long-standing nephropathic cystinosis found no signs of peripheral nervous system dysfunction in 14 patients examined, although 93% (13/14) showed either clinical or neuroradiologic abnormality of their central nervous system.[13] To the best of our knowledge, pathologic findings in peripheral nerves in patients with cystinosis have not been described.

We found cystinosis patients to have normal nerve conduction velocities, electrocardiogram R-to-R variability, and blink reflex latencies. Nephropathic cystinosis appears to spare the neural mechanisms involved in these electrophysiologic tests.

Two interesting findings were the relative intolerance to blink reflex testing found in many of the subjects, and the precipitation of a sneeze following supraorbital nerve stimulation in two of the four patients who tolerated testing. Patients with cystinosis have an increased prevalence of the photic-induced sneeze reflex.[8,9] The photic-induced sneeze reflex is believed to be caused by optic-trigeminal summation or optic nerve-enhanced irritability of the trigeminal nerve.[8,9] Patients with cystinosis may have an underlying irritability of the trigeminal nerve, declared clinically as an increased prevalence of photic or supraorbital nerve stimulation-precipitated sneeze. Patients with cystinosis have been reported to show trigeminal dysfunction[7-9]

Most patients with cystinosis would be expected to show grossly normal neurologic function, moderate generalized hypotonia in the presence of normal or even brisk deep tendon reflexes, and gross and fine motor incoordination. A smaller than average head circumference is also common. Our neurophysiologic studies suggest that the peripheral nervous system is relatively spared in nephropathic cystinosis. Peripheral nerve electrophysiologic studies are, however, only a gross measure of peripheral nerve function. There may be subtle peripheral changes not apparent when employing our techniques. Further neuropathologic evaluation of the peripheral nervous system in nephropathic cystinosis may reveal abnormalities not apparent on clinical neurophysiologic evaluation.

Clinical Issues Relating to the Diagnosis of Mild Dementia in a British Community Survey

Daniel W. O'Connor, MD; Penelope A. Pollitt, PhD; John B. Hyde, MRCPsych;
Nigel D. Miller, MRCPsych; Janet L. Fellowes, MRCPsych

• Many epidemiologists base their diagnoses of dementia on scores on brief cognitive tests, but the border between normal aging and mild dementia is so poorly understood that simple demarcations cannot adequately encapsulate the wealth of clinical material that needs to be taken into account in assigning diagnostic labels. Data from a British study of the prevalence and natural history of dementia, in which diagnoses of dementia were made by clinicians using a new, standardized interview schedule, are presented to demonstrate the effects of physical disability, psychiatric illness, and other factors on memory impairment and performance in everyday life. Our purpose is not to insist that clinicians are always correct but rather to highlight the complexities involved and the need for investigators to be more open about the way in which they distinguish between physical, psychiatric, and cognitive infirmities.

(*Arch Neurol.* 1991;48:530-534)

Prevalence rates for advanced dementia show a fair degree of uniformity from study to study but rates for mild dementia vary widely, largely because of differences in definition.[1] Community surveys have become so expensive that many researchers base their diagnoses on brief cognitive tests, but two major difficulties follow from this. First, simple tests that focus on orientation and general knowledge were devised for use in hospitals and fail to detect a substantial proportion of community-resident demented people who tend to be much less severely affected.[2] In addition, cognitively intact old people do badly on tests for many reasons, including poor concentration, low intelligence, deafness, aphasia, depression, and physical illness and many will be wrongly labeled as demented if diagnoses are based on test scores alone.[3,4]

Second, the *Diagnostic and Statistical Manual of Mental Disorders, Revised Third Edition,* now defines dementia as a degree of cognitive impairment that is sufficient to interfere with social and occupational function.[5] This is important because demented persons cannot provide an accurate account of their own abilities so that independent evidence is required if the criteria are to be applied correctly. Clinicians take histories from relatives as a matter of course, but epidemiologists have been loathe to follow suit, partly for economic reasons and partly through fear that relatives will attribute forgetfulness and loss of mental sharpness to normal aging and fail to report these conditions.[6] Whether this occurs in practice, however, remains to be seen.

The concept of mild dementia is relatively new and few investigators have the time and the money to follow up subjects over lengthy periods. It comes as no surprise that clinical validity is less than perfect, although mistakes are frequently just as revealing as "correct hits." When Bergmann and colleagues[7] traced subjects diagnosed as having mild or questionable dementia, six had died, three were clearly demented, and seven had improved but, significantly, four of the seven appeared to have been of lower than average intelligence in earlier life. In another British study, only six of 12 persons diagnosed as having mild organic impairment using the Geriatric Mental State Examination were judged to be demented 1 year later. Of the remainder, two were depressed, one had developed schizophrenia, and three were classified as normal.[8]

Clearly, low intelligence and functional psychiatric disorders obscure the clinical picture. This analysis seeks to unravel the effects of these and other factors using data from a longitudinal study in Cambridge, England, in which dementia was diagnosed using a comprehensive, standardized interview schedule, and operational criteria. We describe the clinical characteristics that persuaded psychiatrists to diagnose dementia in the absence of marked cognitive or behavioral deficits or to pass as normal individuals whose performance was consistent with dementia, with a view to highlighting important features that might be overlooked in surveys based on simple measures of cognitive function.

SUBJECTS AND METHODS

Patients aged 75 years and older on April 1, 1986, who were registered with six Cam-

bridge general practices were screened over a 12-month period by trained lay interviewers who administered the Mini-Mental State Examination[9]; findings from a seventh practice have been excluded because the test was administered in a slightly different way and the results are not directly comparable. Patients who scored 23 or less of a maximum score of 30 points, together with a one in three sample of those who scored 24 or 25 points, were then assessed by psychiatrists using the Cambridge Examination for Mental Disorders of the Elderly (CAMDEX).[10] The CAMDEX is a lengthy, structured interview that comprises a mental state examination, detailed cognitive tests, a medical and psychiatric history, a physical examination, and an interview with an informant (usually the closest relative) that inquires about changes in memory, intellect, and behavior and the duration and course of symptoms.

The CAMDEX incorporates criteria for dementia, delirium, and major depressive disorders. Diagnoses of dementia were based on the total clinical picture and required (1) a failure in performance in everyday activities, not due to physical illness or handicap, (2) an impairment of memory, and (3) a deterioration of personality or general intellectual capacity or disturbance of higher cortical function. Criteria for mild dementia included "difficulty in recalling recent information; limited or patchy disorientation to time and place; impaired problem solving, reasoning, and capacity to manage everyday activities, and diminished clarity of speech." The CAMDEX also includes the category of minimal or questionable dementia. Minimally demented subjects, who failed to satisfy criteria for dementia proper, were described as having "a limited and variable impairment in recalling recent events; minor and variable errors in orientation; some blunting of reasoning and problem solving; and occasional errors in occupational tasks."

The analysis examines the scores of nondemented, minimally demented, and mildly demented subjects on two measures of memory and behavior taken from CAMDEX. Similar findings would doubtless emerge whatever indexes were used—the importance of the analysis lies in the level of agreement between subjects' broad positions on the scales and the judgments made by experienced clinicians. The memory scale comprised a series of short-term memory tests (recall of three words, a five-item name and address, and six photographs and recall of the photographs when presented later), which required that subjects be able to hear, to see the photographs, and to write a name and address on an envelope (missed items were scored as zero). The behavioral measure, the Blessed-Roth Dementia Scale, consists of questions put to informants about memory, orientation, and personal care.[11] Maximum scores on the memory tests and dementia scale were 20 and 34 points, respectively. The Blessed-Roth scale specifies that allowance be made for physical disabilities and illnesses that restrict activities[11] but, in this study, informants were asked about what subjects actually managed, not what they might have managed in different circumstances. For this reason, the Blessed-Roth Dementia Scale will be referred herein as the "disability scale."

The method used to highlight subjects who posed, or might have posed, diagnostic difficulties was simple. Scores on both scales were divided as closely as possible into the lowest third, an intermediate group, and the highest third, and the groups were then cross-tabulated. The majority of subjects occupied obvious positions; most mildly demented subjects, for example, performed badly on memory tests and their informants reported changes in memory, orientation, and personal care, but we focused on subjects who occupied anomalous or intermediate positions.

Demented subjects were reviewed 1 and 2 years later using the same procedures. Diagnoses were confirmed for all surviving moderately or severely demented cases, and for 63 of 67 surviving, mildly demented cases at 1 year and for 55 of 57 who were seen at 2 years.[12] Six of 29 minimally demented respondents who were reviewed at 1 year and 12 of 24 survivors who were reviewed at 2 years showed evidence of cognitive deterioration. However, the fact that 13 minimal cases were regraded as normal 1 year later suggests that diagnoses at this early stage have limited validity, at least under field conditions, and the results that follow concern the normal and mildly impaired groups. As our findings make clear, "normal" subjects were often far from normal in the usual sense but we used the term as shorthand for "nondemented" or "presumably nondemented."

RESULTS

Study Population

The response rate in the screening phase of the study was 90% (2311/2569); 196 patients refused to be seen, 48 could not be traced, and 14 were too ill to be interviewed. The response rate in the diagnostic phase was 82% (481/586); 68 eligible patients refused, 16 had died, and 21 could not be traced or were missed in error.[13] Relatives or other informants were interviewed for 89% (430/481) of the subjects assessed using CAMDEX; 13 had no surviving family, eight refused permission, three informants chatted informally but refused or were unable to answer every question, seven could not be contacted, and 20 lived too far away to be visited.

Complete information was available therefore for 182 subjects judged to be cognitively intact, for 40 minimally demented subjects, and for 91 mildly demented subjects (the remaining 117 subjects were moderately or severely demented). Table 1 shows that subjects were generally very old and that most were female. A larger proportion of normal subjects had worked in semiskilled or unskilled occupations because of bias in the screening test. As a result of this bias, working-class respondents were particularly likely to score below the specified cut-point, despite the fact that they were no more likely to be diagnosed as demented than those from more privileged backgrounds.[4,14]

Table 1.—Demographic Characteristics of Normal, Minimally, and Mildly Demented Subjects

	Normal, n=182	Minimal Dementia, n=40	Mild Dementia, n=91
Mean age	82.4	85.5	84.3
(SD)	(4.7)	(6.1)	(4.9)

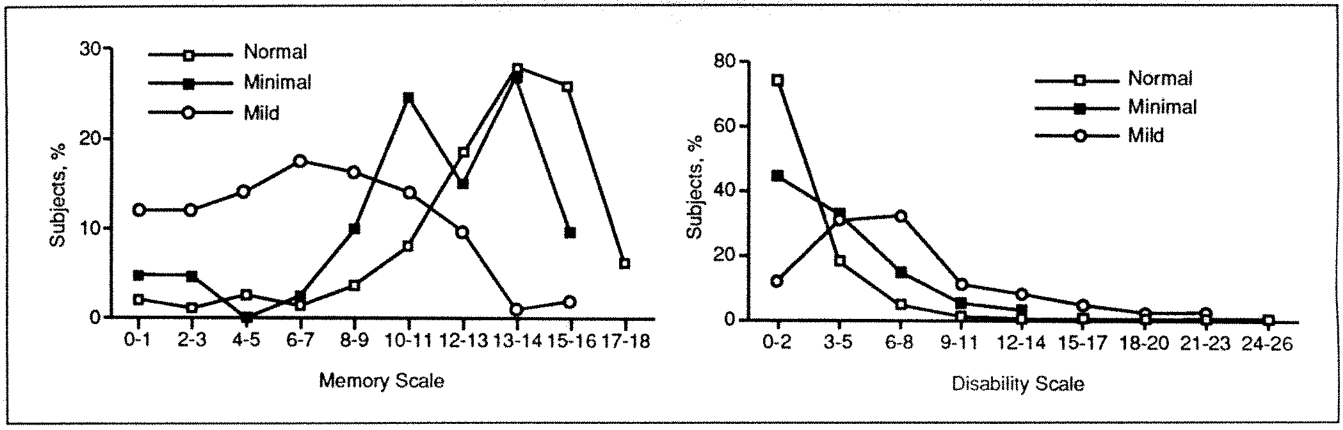
Score Distributions

The Figure shows scores of normal, minimally demented, and mildly demented subjects on the memory and Blessed-Roth disability scales. Note that the scales work in opposite directions since active, mentally alert subjects should normally achieve high memory scores but low disability scores, while demented subjects should normally have low memory scores but higher disability scores. Memory scores covered a wide range and were generally high, while disability scores covered a narrower range and were generally low. Predictably, memory scores declined with advancing levels of dementia from a mean value of 13.5 (SD ± 3.8) for normal subjects to 11.0 (±4.0) for minimally demented subjects and 6.8 (±4.1) for mildly demented subjects (Kruskall-Wallis test, $P < .00005$). Conversely, disability scores increased from 1.9 (±3.0) to 3.5 (±3.1) and 6.8 (±4.2) for normal, minimally, and mildly demented subjects, respectively ($P < .00005$). Even so, there was a marked overlap in scores on both scales.

Diagnoses vs Test Scores

Table 2 lists the numbers of normal, minimally, and mildly demented subjects with high, intermediate, and low scores on the memory and Blessed-Roth disability scales. As expected, most normal subjects lie in the top



Scores on the memory and Blessed-Roth disability scales for normal, minimally, and mildly demented subjects.

left-hand corner of the table (good memory, low disability), while most mildly demented subjects lie in the bottom right-hand corner (poor memory, high disability). A simple classification system based on the three cells in the bottom right-hand corners performed surprisingly well in distinguishing between normal and minimally demented subjects on the one hand and mildly demented subjects on the other. Cells 6, 8, and 9 contain 91% (83/91) of the mildly demented group, while the remaining cells contain 84% (187/222) of the normal and minimally demented groups. However, as many as 30% (35/118) of subjects in cells 6, 8, and 9 were judged to be normal or minimally demented and the remainder of this section concerns respondents who occupy anomalous positions. For convenience, subjects have been divided into seven groups according to their positions in Table 2.

Table 2.—Distribution of Trisected Scores on the Memory and Blessed-Roth Disability Scales for Normal, Minimally, and Mildly Demented Subjects*

	Memory Scores								
	Normal, n=182			**Minimal Dementia, n=40**			**Mild Dementia, n=91**

High	6_7	8_8	3_9	1_7	3_8	7_9	2_7	14_8	51_9

*Cell numbers are subscripted. Minus signs indicate 0.

Group A

Twenty-two normal respondents had poor or intermediate memory scores and high or intermediate scores on the Blessed-Roth disability scale (cells 6, 8, or 9). Six had major depressive illnesses and seemed to do badly on testing because of poor concentration and motivation. Four of them gained points on the disability scale, not because of cognitive impairment, but because of their need for prompting and supervision and, in one case, because of urinary incontinence that had been present for many years following surgery.

Three respondents did badly on testing and needed help with everyday tasks because of blindness, deafness, aphasia, or physical incapacity. Of the remainder, two were delirious; one was mentally handicapped but continued to function at her usual low level; one was of limited intellect and had always needed help with shopping and paying bills, and two had chronic, relapsing manic-depressive psychoses. An elderly man who did badly on one memory test, but satisfactorily on the others, was described by his son as having great difficulty in recalling recent events. This was at odds with the psychiatrist's own assessment but, as the son had failed to visit his father for more than 1 year, his opinion was overruled. Finally, one profoundly deaf man looked vague and perplexed, did badly on testing, and was said by his wife to be forgetful and muddled. She retracted this later, claiming that he managed the garden and odd jobs around the house. This seemed highly implausible given his marked physical frailty, but his poor performance was attributed to deafness. In retrospect, however, he was almost certainly dementing.

Group B

Fifteen normal subjects did badly on testing, but received low disability scores (cell 3). There were obvious reasons for the discrepancy in 11 cases, including depression, chronic schizophrenia, blindness, deafness, terminal cancer, limited English, and illiteracy coupled with extreme anxiety. The psychiatrist considered the possibility of an amnestic disorder in the case of a difficult, uncooperative man with a long history of alcohol abuse but his daughter dismissed his forgetfulness as just another sign of his "lazy, good-for-nothing ways." Unfortunately, he died before he could be reviewed and his true status remains unknown. The five remaining subjects, who were described as being occasionally forgetful, were all bright and lively and perfectly capable of managing their own affairs.

Group C

Six normal old people did well on testing but had high disability scores (cell 7), usually because of physical infirmity. Three had had strokes, one was partially sighted and deaf, and two were ill but their informants denied any mental changes.

Group D

Twenty-two normal subjects scored in the middle range on both scales (cell 5). Six had difficulty completing the memory tests because of a physical handicap and received higher than average scores on the disability scale for the same reason. Another five were physically handicapped and depressed; one was delirious; one had an organic personality disorder following a stroke and one spoke so little English that she had difficulty understanding the questions put to her. Two women, who had always been clinging and dependent, became anxious on testing, refused to exert themselves, and simply gave up. The remaining five subjects were said to be occasionally forgetful but their lapses were of no practical consequence and they appeared to the interviewers to be bright, alert, and fully in touch with recent events.

Group E

One diabetic woman who was rated as mildly demented scored in the middle range on memory tests and had a low disability score (cell 3). This seems anomalous but she was also disoriented to time, and her daughter reported a 10-year history of gradually progressive apathy, withdrawal, and declining personal standards. However, when she was seen 1 year later, her insulin-dependent diabetes had come under better control, she was much more responsive, and she did better on testing. The psychiatrist reclassified her as minimally impaired but, in hindsight, her mental impairment had probably been exacerbated by hyperglycemia at the time of her first assessment.

Group F

Two mildly demented subjects received low disability scores (cell 3). One had a congenital deformity and had always been cared for by a younger sibling. The latter acknowledged a degree of forgetfulness and indecisiveness, but she explained these changes in physical terms, presumably out of habit. In the other case, a simple, poorly educated man denied that his wife had deteriorated despite the fact that she failed every memory test and could not recall what had happened earlier that day. He had gradually taken over responsibility of running the house but he enjoyed this so much and made so few demands of his spouse that he seemed genuinely not to notice what was apparent to the psychiatrist within a minute or two of meeting her.

Group G

The two seemingly mildly demented women who performed well on memory tests but received high disability scores were of particular interest (cell 7). One had a long history of depression and described a number of depressive symptoms, but the interviewer was struck by her inertia and perplexity, her disorientation to time, and her marked constructional dyspraxia. The nursing home officer who had known her for many years reported that she was difficult, demanding, and occasionally muddled in her thinking, but otherwise mentally intact. In retrospect, it seems highly likely, in view of her good performance on memory tests, that she was depressed with secondary cognitive impairment and that her dyspraxia was due to the focal effects of a small stroke sustained several years previously but, unfortunately, she moved away and could not be reviewed.

Important clinical features may have been missed in the case of another elderly woman who was judged to be demented despite her good performance on testing. She looked bewildered at the time of her first assessment, her speech was rambling and repetitive, and her daughter described fluctuating disorientation and confusion. She was profoundly demented 2 years later, but it was noticed when compiling this report that her symptoms had developed after a blow to her head, which raises the possibility of a chronic subdural hematoma. The interviewer was correct to attend to the informant's report of variable confusion but remiss in failing to attend to its practical implications.

COMMENT

The methods used to examine the impact of functional psychiatric illness, physical infirmity, and the perceptiveness of informants are contrived but, despite this, they serve to highlight a number of important points. Subjects rated as cognitively intact achieved significantly better scores on the average than mildly demented people, but the overlap in memory and behavioral scores was so marked that demarcations based on absolute levels of performance would have resulted in many erroneous diagnoses. The same applies to a rudimentary classification based on trisected scores. This worked much better than expected, bearing in mind that respondents who scored 26 points or more on the Mini-Mental State Examination were excluded together with those who were markedly demented but, even so, 30% of subjects whose scores fell within the relevant cells (cell 6, 8, or 9) failed to meet the criteria for mild dementia.

Berg and colleagues[16] have shown that mild dementia, and even very mild dementia, can be reliably and validly diagnosed in carefully selected hospital populations. As in our study, psychometric scores were of limited value in themselves,[15] but standardized ratings based on detailed assessments were in striking accord with autopsy findings.[16-18] Subjects with physical, neurologic, or psychiatric disorders were excluded from their studies[16-18] but epidemiologists are required to make a judgment in the case of every person seen and they frequently contend with difficult and confusing presentations.

Clinical assessments have the advantage that many different factors can be considered, but complex judgments based on subjects' backgrounds, social circumstances, and physical health open the way to low levels of interobserver reliability. The *Diagnostic and Statistical Manual of Mental Disorders, Revised Third Edition* and CAMDEX criteria have much in common; they specify the types and numbers of abnormalities required for diagnosis but they lack clear anchor points, and clinicians working in different centers might arrive at different interpretations.[19] Individual research teams can achieve high levels of agreement. The CAMDEX interviewers, for example, assigned identical diagnoses and severity levels in 20 of 23 joint interviews but, significantly, all three disagreements related to minimal and mild dementia.[20] Similarly, when a random selection of 20 CAMDEX schedules from each of the five severity ratings was rated blindly using the Clinical Dementia Rating scale,[21] the level of agreement was acceptably high at 75%. However, six of the 20 subjects who were classified as normal by CAMDEX were rated as questionably demented on the Clinical Dementia Rating Scale and two were rated as mildly demented.[20]

Premorbid ability, mood, motivation, sensory deficits, and physical incapacity must all be considered when attempting to distinguish between normal aging and mild dementia, although it is difficult to conceive of any system capable of distinguishing between the two with perfect reliability and validity in unselected populations. A dimensional view of dementia, which separates "cases" from "noncases," requires that failure to answer a question because of deafness, for example, be distinguished from failure due to organic mental disorder, but deafness and dementia both increase with age and many demented people are also deaf.[22] Clearly, the way in which this problem is resolved will determine who is and who is not classified as demented.

Informants' accounts were highly consistent with other independent measures of cognition and behavior and proved immensely helpful in making sense of complex cases.[23] Historical information is essential if people suffering from schizophrenia, amnestic disorders, delirium, and other disabilities are to be classified correctly but, clearly, small numbers of relatives provided misleading answers, usually through ignorance or emotional bias.[23] In addition, informants will sometimes minimize early mental changes or attribute them to laziness or awkwardness but, as before, these differences in sensitivity and attribution will be felt most keenly at the borderline between normal aging and mild cognitive impairment.

Dementia can also be seen as part of a continuum, in the sense that no clear boundaries exist between normal mental function; minor lapses of memory and judgment that are of no practical consequence, at least for the present; and early dementia. Scores on memory tests and behavioral ratings are smoothly and continuously distributed in representative samples[24] and the numbers of senile plaques and neurofibrillary tangles found at autopsy increase smoothly and continuously with advancing age.[25,26] Indeed, it seems likely that a sizable proportion of the normal subjects considered in this study, who had all scored 25 points or less on the Mini-Mental State Examination, had a greater than average number of plaques, tangles, infarctions, and other lesions for their age, but not in sufficient numbers to produce clinical decompensation.[27,28]

This is not to say that dementia does not exist. It does exist and efforts to diagnose dementia in its early stages will assume particular significance should pharmacologic treatments become available. The dividing line between normality and early dementia might prove to be considerably more fluid than expected, however, and clinical findings of the kind we presented will be of great importance if assessment procedures and diagnostic criteria are to be improved. Brief assessment procedures cannot do justice to the complex data that need to be considered and they provide so little information that researchers will have difficulty in tracing the factors responsible for diagnostic errors. Detailed clinical assessments, informant reports, prolonged follow-up, and the reporting of inconsistencies in presentation and outcome will be of great help in filling this vacuum.

The Hughes Hall Project for Later Life was funded by the Charles Wolfson Charitable Trust.

We thank Beryl Jones for help with Cambridge Examination for Mental Disorders of the Elderly or diagnostic interviews; Bobbie Coe for data entry; Peter Brook, FRCPsych, and Bernard Reiss, FRCGP, for supervision and Basil Herbertson, MD, and Sir Martin Roth, MD, for their support and advice.

HEADACHE DESCRIBED

"Headache"– a personal interpretation of headache pain by John Crowley, a headache patient.

HEADACHE RELIEVED

Effectively treats the pain of muscle contraction headache as well as the anxiety and tension that magnify it

FIORINAL® WITH CODEINE CAPSULES Ⓒ III

(Each capsule contains: codeine phosphate 30 mg [Warning: May be habit-forming]; butalbital 50 mg [Warning: May be habit-forming], caffeine 40 mg; and aspirin 325 mg)

Potent relief of tension headache pain

Please see brief summary on following page.

SANDOZ

SANDOZ PHARMACEUTICALS CORPORATION
EAST HANOVER, NEW JERSEY 07936

5/91 Printed in U.S.A. FWC-1290-01

BRIEF SUMMARY: Please see package insert for full prescribing information.

FIORINAL® WITH CODEINE III CAPSULES

(Codeine phosphate USP, 30 mg [warning: may be habit forming], butalbital USP, 50 mg [warning: may be habit forming]; caffeine USP, 40 mg; aspirin USP, 325 mg)

CAUTION: Federal law prohibits dispensing without prescription.

CONTRAINDICATIONS: Fiorinal® with Codeine is contraindicated under the following conditions:

1. Hypersensitivity or intolerance to aspirin, caffeine, butalbital or codeine.
2. Patients with a hemorrhagic diathesis (e.g., hemophilia, hypoprothrombinemia, von Willebrand's disease, the thrombocytopenias, thrombasthenia and other ill-defined hereditary platelet dysfunctions, severe vitamin K deficiency and severe liver damage.)
3. Patients with the syndrome of nasal polyps, angioedema and bronchospastic reactivity to aspirin or other nonsteroidal anti-inflammatory drugs. Anaphylactoid reactions have occurred in such patients.
4. Peptic ulcer or other serious gastrointestinal lesions.
5. Patients with porphyria.

WARNINGS: Therapeutic doses of aspirin can cause anaphylactic shock and other severe allergic reactions. It should be ascertained if the patient is allergic to aspirin, although a specific history of allergy may be lacking.

Significant bleeding can result from aspirin therapy in patients with peptic ulcer or other gastrointestinal lesions, and in patients with bleeding disorders.

Aspirin administered pre-operatively may prolong the bleeding time.

In the presence of head injury or other intracranial lesions, the respiratory depressant effects of codeine and other narcotics may be markedly enhanced, as well as their capacity for elevating cerebrospinal fluid pressure. Narcotics also produce other CNS depressant effects, such as drowsiness, that may further obscure the clinical course of patients with head injuries.

Codeine or other narcotics may obscure signs on which to judge the diagnosis or clinical course of patients with acute abdominal conditions.

Butalbital and codeine are both habit-forming and potentially abusable. Consequently, the extended use of Fiorinal® with Codeine is not recommended.

Results from epidemiologic studies indicate an association between aspirin and Reye Syndrome. Caution should be used in administering this product to children, including teenagers, with chicken pox or flu.

PRECAUTIONS: **General:** Fiorinal® with Codeine should be prescribed with caution for certain special-risk patients such as the elderly or debilitated, and those with severe impairment of renal or hepatic function, coagulation disorders, or head injuries.

Aspirin should be used with caution in patients on anticoagulant therapy and in patients with underlying hemostatic defects.

Precautions should be taken when administering salicylates to persons with known allergies. Hypersensitivity to aspirin is particularly likely in patients with nasal polyps, and relatively common in those with asthma.

Information for Patients: Patients should be informed that Fiorinal® with Codeine contains aspirin and should not be taken by patients with an aspirin allergy.

Fiorinal® with Codeine may impair the mental and/or physical abilities required for performance of potentially hazardous tasks such as driving a car or operating machinery. Such tasks should be avoided while taking Fiorinal® with Codeine.

Alcohol and other CNS depressants may produce an additive CNS depression when taken with Fiorinal® with Codeine, and should be avoided.

Codeine and butalbital may be habit-forming. Patients should take the drug only for as long as it is prescribed, in the amounts prescribed, and no more frequently than prescribed.

Laboratory Tests: In patients with severe hepatic or renal disease, effects of therapy should be monitored with serial liver and/or renal function tests.

Drug Interactions: The CNS effects of butalbital may be enhanced by monoamine oxidase (MAO) inhibitors.

In patients receiving concomitant corticosteroids and chronic use of aspirin, withdrawal of corticosteroids may result in salicylism because corticosteroids enhance renal clearance of salicylates and their withdrawal is followed by return to normal rates of renal clearance.

Fiorinal® with Codeine may enhance the effects of:

1. Oral anticoagulants, causing bleeding by inhibiting prothrombin formation in the liver and displacing anticoagulants from plasma protein binding sites.
2. Oral antidiabetic agents and insulin, causing hypoglycemia by contributing an additive effect, if dosage of Fiorinal® with Codeine exceeds maximum recommended daily dosage.
3. 6-mercaptopurine and methotrexate, causing bone marrow toxicity and blood dyscrasias by displacing these drugs from secondary binding sites, and, in the case of methotrexate, also reducing its excretion.
4. Non-steroidal anti-inflammatory agents, increasing the risk of peptic ulceration and bleeding by contributing additive effects.
5. Other narcotic analgesics, alcohol, general anesthetics, tranquilizers such as chlordiazepoxide, sedative-hypnotics, or other CNS depressants, causing increased CNS depression.

Fiorinal® with Codeine may diminish the effects of: Uricosuric agents such as probenecid and sulfinpyrazone, reducing their effectiveness in the treatment of gout. Aspirin competes with these agents for protein binding sites.

Drug/Laboratory Test Interactions

Aspirin: Aspirin may interfere with the following laboratory determinations in blood: serum amylase, fasting blood glucose, cholesterol, protein, serum glutamic-oxalacetic transaminase (SGOT), uric acid, prothrombin time and bleeding time. Aspirin may interfere with the following laboratory determinations in urine: glucose, 5-hydroxyindoleacetic acid, Gerhardt ketone, vanillylmandelic acid (VMA), uric acid, diacetic acid, and spectrophotometric detection of barbiturates.

Codeine: Codeine may increase serum amylase levels.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Adequate long-term studies have been conducted in mice and rats with aspirin, alone or in combination with other drugs, in which no evidence of carcinogenesis was seen. No adequate studies have been conducted in animals to determine whether aspirin has a potential for mutagenesis or impairment of fertility. No adequate studies have been conducted in animals to determine whether butalbital has a potential for carcinogenesis, mutagenesis, or impairment of fertility.

Usage in Pregnancy

Teratogenic Effects: Pregnancy Category C — Animal reproduction studies have not been conducted with Fiorinal® with Codeine. It is also not known whether Fiorinal® with Codeine can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Fiorinal® with Codeine should be given to a pregnant woman only when clearly needed.

Nonteratogenic Effects: Although Fiorinal® with Codeine was not implicated in the birth defect, a female infant was born with lissencephaly, pachygyria and heterotopic gray matter. The infant was born 8 weeks prematurely to a woman who had taken an average of 90 Fiorinal® with Codeine capsules each month from the first few days of pregnancy. The child's development was mildly delayed and from one year of age she had partial simple motor seizures.

Withdrawal seizures were reported in a two-day-old male infant whose mother had taken a butalbital-containing drug during the last 2 months of pregnancy. Butalbital was found in the infant's serum. The infant was given phenobarbital 5mg/kg, which was tapered without further seizure or other withdrawal symptoms.

Studies of aspirin use in pregnant women have not shown that aspirin increases the risk of abnormalities when administered during the first trimester of pregnancy. In controlled studies involving 41,337 pregnant women and their offspring, there was no evidence that aspirin taken during pregnancy caused stillbirth, neonatal death or reduced birth weight. In controlled studies of 50,282 pregnant women and their offspring, aspirin administration in moderate and heavy doses during the first four lunar months of pregnancy showed no teratogenic effect.

Reproduction studies have been performed in rabbits and rats at doses up to 150 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to codeine.

Therapeutic doses of aspirin in pregnant women close to term may cause bleeding in mother, fetus, or neonate. During the last 6 months of pregnancy, regular use of aspirin in high doses may prolong pregnancy and delivery.

Labor and Delivery: Ingestion of aspirin prior to delivery may prolong delivery or lead to bleeding in the mother or neonate. Use of codeine during labor may lead to respiratory depression in the neonate.

Nursing Mothers: Aspirin, caffeine, barbiturates and codeine are excreted in breast milk in small amounts, but the significance of their effects on nursing infants is not known. Because of potential for serious adverse reactions in nursing infants from Fiorinal® with Codeine, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children below the age of 12 have not been established.

ADVERSE REACTIONS: **Commonly Observed:** The most commonly reported adverse events associated with the use of Fiorinal® with Codeine and not reported at an equivalent incidence by placebo-treated patients were nausea and/or abdominal pain, drowsiness, and dizziness.

Associated with Treatment Discontinuation: Of the 382 patients treated with Fiorinal® with Codeine in controlled clinical trials, three (0.8%) discontinued treatment with Fiorinal® with Codeine because of adverse events. One patient each discontinued treatment for the following reasons: gastrointestinal upset; lightheadedness and heavy eyelids; and drowsiness and generalized tingling.

Incidence in Controlled Clinical Trials: The following table summarizes the incidence rates of the adverse e reported by at least 1% of the Fiorinal® with Codeine treated patients in controlled clinical trials comparing Fior with Codeine to placebo, and provides a comparison to the incidence rates reported by the placebo-treated pati

The prescriber should be aware that these figures cannot be used to predict the incidence of side effe the course of usual medical practice where patient characteristics and other factors differ from those that pre in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other cl investigations involving different treatments, uses, and investigators.

Adverse Events Reported by at Least 1% of Fiorinal® with Codeine Treated Patients During Placebo Controlled Clinical Trials

	Incidence Rate of Adverse Events	
Body System/ Adverse Event	Fiorinal®/Codeine (N = 382)	Place (N =
Central Nervous		
Drowsiness	2.4%	0.5
Dizziness/Lightheadedness	2.6%	0.5
Intoxicated Feeling	1.0%	0%
Gastrointestinal		
Nausea/Abdominal Pain	3.7%	0.8

Other Adverse Events Reported During Controlled Clinical Trials: The listing that follows represents the prop of the 382 patients exposed to Fiorinal® with Codeine while participating in the controlled clinical trials who rep on at least one occasion, an adverse event of the type cited. All reported adverse events, except those a presented in the previous table, are included. It is important to emphasize that, although the adverse events re did occur while the patient was receiving Fiorinal® with Codeine, the adverse events were not necessarily c by Fiorinal® with Codeine

Adverse events are classified by body system and frequency. "Frequent" is defined as an adverse event occurred in at least 1/100 (1%) of the patients; all adverse events listed in the previous table are frequent. "Infre is defined as an adverse event that occurred in less than 1/100 patients but at least 1/1000 patients. All a events tabulated below are classified as infrequent.

Central Nervous: headache, shaky feeling, tingling, agitation, fainting, fatigue, heavy eyelids, high energy, hot numbness, and sluggishness.

Autonomic Nervous: dry mouth and hyperhidrosis.

Gastrointestinal: vomiting, difficulty swallowing, and heartburn.

Cardiovascular: tachycardia.

Musculoskeletal: leg pain and muscle fatigue.

Genitourinary: diuresis.

Miscellaneous: pruritus, fever, earache, nasal congestion, and tinnitus.

Voluntary reports of adverse drug events, temporally associated with Fiorinal® with Codeine, that have been re since market introduction and that were not reported in clinical trials by the patients treated with Fiorinal Codeine, are listed below. Many or most of these events may have no causal relationship with the drug an listed according to body system.

Central Nervous: Abuse, addiction, anxiety, depression, disorientation, hallucination, hyperactivity, insomnia, decrease, nervousness, neuropathy, psychosis, sedation, sexual activity increase, slurred speech, twitching, u sciousness, vertigo.

Autonomic Nervous: epistaxis, flushing, miosis, salivation.

Gastrointestinal: anorexia, appetite increased, constipation, diarrhea, esophagitis, gastroenteritis, gastroint spasm, hiccup, mouth burning, pyloric ulcer.

Cardiovascular: chest pain, hypotensive reaction, palpitations, syncope.

Skin: erythema, erythema multiforme, exfoliative dermatitis, hives, rash, toxic epidermal necrolysis.

Urinary: kidney impairment, urinary difficulty.

Miscellaneous: allergic reaction, anaphylactic shock, cholangiocarcinoma, drug interaction with erythr (stomach upset), edema.

The following adverse drug events may be borne in mind as potential effects of the components of Fi with Codeine. Potential effects of high dosage are listed in the *OVERDOSAGE* section of this insert.

Aspirin: occult blood loss, hemolytic anemia, iron deficiency anemia, gastric distress, heartburn, nausea, ulcer, prolonged bleeding time, acute airway obstruction, renal toxicity when taken in high doses for pro periods, impaired urate excretion, hepatitis.

Caffeine: cardiac stimulation, irritability, tremor, dependence, nephrotoxicity, hyperglycemia.

Codeine: nausea, vomiting, drowsiness, lightheadedness, constipation, pruritus.

DRUG ABUSE AND DEPENDENCE: Fiorinal® with Codeine is controlled by the Drug Enforcement Adminis and is classified under Schedule III.

Codeine: Codeine can produce drug dependence of the morphine type and, therefore, has the poten being abused. Psychological dependence, physical dependence, and tolerance may develop upon re administration and it should be prescribed and administered with the same degree of caution appropriate use of other oral narcotic medications.

Butalbital: *Barbiturates may be habit forming:* Tolerance, psychological dependence, and physical depe may occur especially following prolonged use of high doses of barbiturates. The average daily dose for the bar addict is usually about 1,500 mg. As tolerance to barbiturates develops, the amount needed to maintain the level of intoxication increases; tolerance to a fatal dosage, however, does not increase more than two-fold. occurs, the margin between an intoxication dosage and fatal dosage becomes smaller. The lethal dose of a bar is far less if alcohol is also ingested. Major withdrawal symptoms (convulsions and delirium) may occur wi hours and last up to 5 days after abrupt cessation of these drugs. Intensity of withdrawal symptoms gradually d over a period of approximately 15 days. Treatment of barbiturate dependence consists of cautious and withdrawal of the drug. Barbiturate-dependent patients can be withdrawn by using a number of different wit regimens. One method involves initiating treatment at the patient's regular dosage level and gradually dec the daily dosage as tolerated by the patient.

OVERDOSAGE: The toxic effects of acute overdosage of Fiorinal® with Codeine capsules are attributable to the barbiturate and codeine components, and, to a lesser extent, aspirin. Because toxic effects of caffein in very high dosages only, the possibility of significant caffeine toxicity from Fiorinal® with Codeine over is unlikely.

Signs and Symptoms: Symptoms attributable to *acute barbiturate poisoning* include drowsiness, confusi coma; respiratory depression; hypotension; shock. Symptoms attributable to *acute aspirin poisoning* include hyp acid-base disturbances with development of metabolic acidosis; vomiting and abdominal pain; tinnitus, hypert hypoprothrombinemia; restlessness; delirium; convulsions. *Acute caffeine poisoning* may cause insomnia, restle tremor, and delirium; tachycardia and extrasystoles. Symptoms of *acute codeine poisoning* include the triad of: pupils, marked depression of respiration, and loss of consciousness. Convulsions may occur.

Treatment: The following paragraphs describe one approach to the treatment of overdose with Fiorina Codeine. However, because strategies for the management of an overdose continually evolve, consultation regional poison control center is strongly encouraged.

Treatment consists primarily of management of barbiturate intoxication, reversal of the effects of codei the correction of the acid-base imbalance due to salicylism. Vomiting should be induced mechanically or with in the conscious patient. Gastric lavage may be used if the pharyngeal and laryngeal reflexes are pres if less than 4 hours have elapsed since ingestion. A cuffed endotracheal tube should be inserted before lavage of the unconscious patient and when necessary to provide assisted respiration. Diuresis, alkalini the urine, and correction of electrolyte disturbances should be accomplished through administration of intr fluids such as 1% sodium bicarbonate and 5% dextrose in water.

Meticulous attention should be given to maintaining adequate pulmonary ventilation. Correction of hyp may require the administration of levarterenol bitartrate or phenylephrine hydrochloride by intravenous inf severe cases of intoxication, peritoneal dialysis, hemodialysis, or exchange transfusion may be li Hypoprothrombinemia should be treated with vitamin K, intravenously.

Methemoglobinemia over 30% should be treated with methylene blue by slow intravenous administration.

Naloxone, a narcotic antagonist, can reverse respiratory depression and coma associated with opioid o Typically, a dose of 0.4 mg to 2 mg is given parenterally and may be repeated if an adequate respons achieved. Since the duration of action of codeine may exceed that of the antagonist, the patient should under continued surveillance and repeated doses of the antagonist should be administered as needed to adequate respiration. A narcotic antagonist should not be administered in the absence of clinically significant re or cardiovascular depression.

Toxic and Lethal Doses:

Butalbital: toxic dose 1.0 g (adult); lethal dose 2.0-5.0 g
Aspirin: toxic blood level greater than 30 mg/100 mL; lethal dose 10-30 g (adult)
Caffeine: toxic dose greater than 1.0 g; lethal dose unknown
Codeine: lethal dose 0.5-1.0 g (adult)

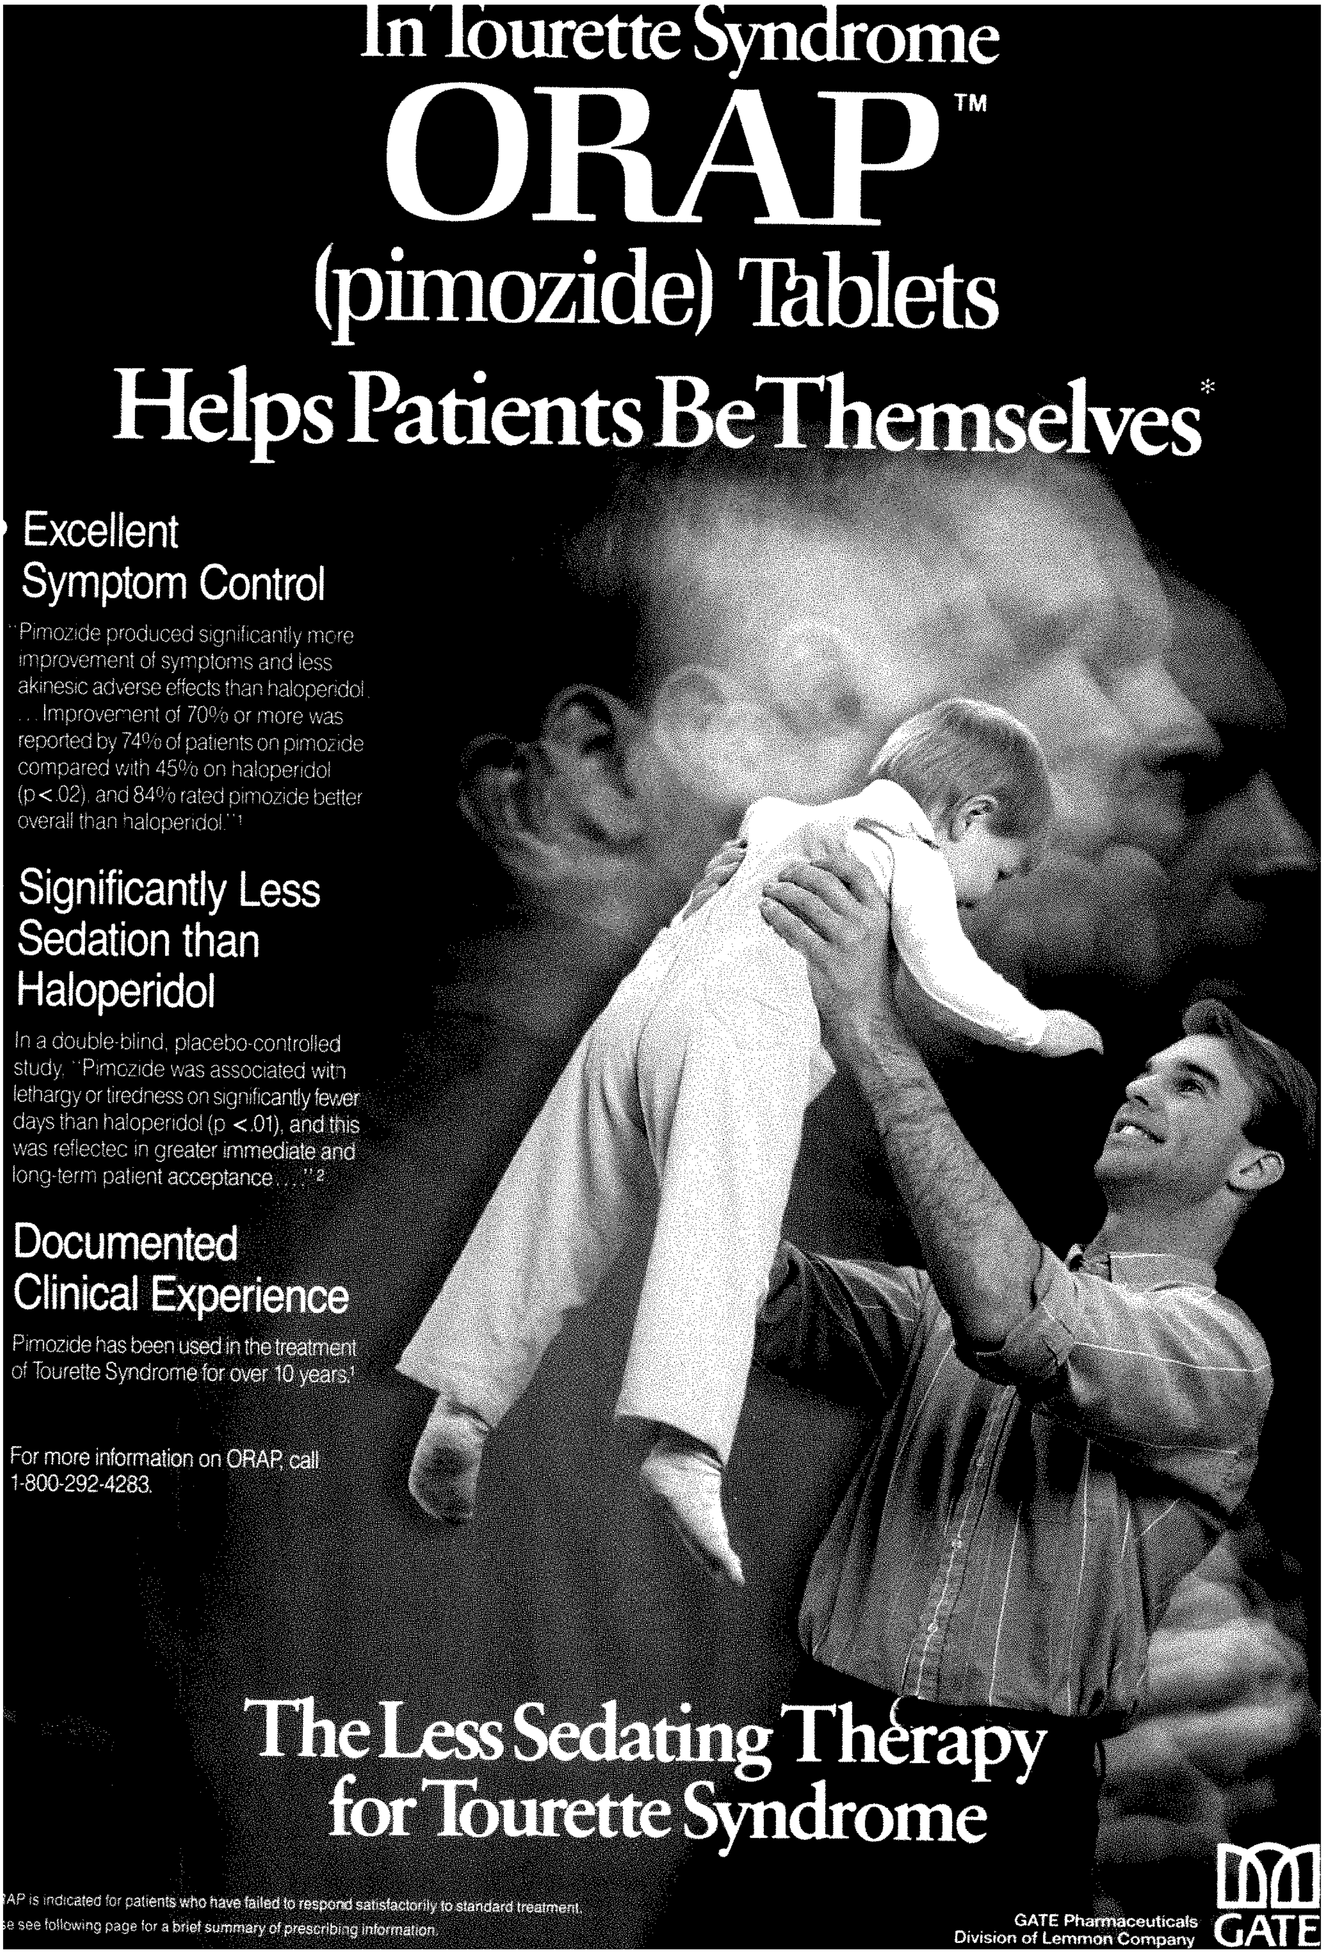
[NOVEMBER 1, 1990 FW



In Tourette Syndrome

ORAP™

(pimozide) Tablets

Helps Patients Be Themselves*

- **Excellent Symptom Control**

"Pimozide produced significantly more improvement of symptoms and less akinesic adverse effects than haloperidol. . . . Improvement of 70% or more was reported by 74% of patients on pimozide compared with 45% on haloperidol ($p < .02$), and 84% rated pimozide better overall than haloperidol."[1]

Significantly Less Sedation than Haloperidol

In a double-blind, placebo-controlled study, "Pimozide was associated with lethargy or tiredness on significantly fewer days than haloperidol ($p < .01$), and this was reflected in greater immediate and long-term patient acceptance. . . ."[2]

Documented Clinical Experience

Pimozide has been used in the treatment of Tourette Syndrome for over 10 years.[1]

For more information on ORAP, call
1-800-292-4283.

The Less Sedating Therapy
for Tourette Syndrome

AP is indicated for patients who have failed to respond satisfactorily to standard treatment.

GATE

ORAP™ The Less Sedating Therapy for Tourette Syndrome

(pimozide) Tablets

INDICATIONS AND USAGE

ORAP (pimozide) is indicated for the suppression of motor and phonic tics in patients with Tourette's Disorder who have failed to respond satisfactorily to standard treatment. ORAP is not intended as a treatment of first choice nor is it intended for the treatment for tics that are merely annoying or cosmetically troublesome. ORAP should be reserved for use in Tourette's Disorder patients whose development and/or daily life function is severely compromised by the presence of motor and phonic tics.

Evidence supporting approval of pimozide for use in Tourette's Disorder was obtained in two controlled clinical investigations which enrolled patients between the ages of 8 and 53 years. Most subjects in the two trials were 12 or older.

CONTRAINDICATIONS

1. ORAP (pimozide) is contraindicated in the treatment of simple tics or tics other than associated with Tourette's Disorder.
2. ORAP should not be used in patients taking drugs that may, themselves, cause motor and phonic tics (e.g., pemoline, methylphenidate and amphetamines) until such patients have been withdrawn from these drugs to determine whether or not the drugs, rather than Tourette's Disorder, are responsible for the tics.
3. Because ORAP prolongs the QT interval of the electrocardiogram it is contraindicated in patients with congenital long QT syndrome, patients with a history of cardiac arrhythmias, or patients taking other drugs which prolong the QT interval of the electrocardiogram (see DRUG INTERACTIONS).
4. ORAP is contraindicated in patients with severe toxic central nervous system depression or comatose states from any cause.
5. ORAP is contraindicated in patients with hypersensitivity to it. As it is not known whether cross-sensitivity exists among the antipsychotics, pimozide should be used with appropriate caution in patients who have demonstrated hypersensitivity to other antipsychotic drugs.

WARNINGS

The use of ORAP (pimozide) in the treatment of Tourette's Disorder involves different risk/benefit considerations than when antipsychotic drugs are used to treat other conditions. Consequently, a decision to use ORAP should take into consideration the following: (see also PRECAUTIONS–Information for Patients).

Tardive Dyskinesia A syndrome consisting of potentially irreversible, involuntary, dyskinetic movements may develop in patients treated with antipsychotic drugs. Although the prevalence of the syndrome appears to be highest among the elderly, especially elderly women, it is impossible to rely upon prevalence estimates to predict, at the inception of antipsychotic treatment, which patients are likely to develop the syndrome. Whether antipsychotic drug products differ in their potential to cause tardive dyskinesia is unknown.

Both the risk of developing tardive dyskinesia and the likelihood that it will become irreversible are believed to increase as the duration of treatment is withdrawn. Antipsychotic treatment, itself, however, may suppress (or partially suppress) the signs and symptoms of the syndrome and thereby may possibly mask the underlying process. The effect that symptomatic suppression has upon the long-term course of the syndrome is unknown.

Given these considerations, antipsychotic drugs should be prescribed in a manner that is most likely to minimize the occurrence of tardive dyskinesia. Chronic antipsychotic treatment should generally be reserved for patients who suffer from a chronic illness that, 1) is known to respond to antipsychotic drugs, and, 2) for whom alternative, equally effective, but potentially less harmful treatments are not available or appropriate. In patients who do require chronic treatment, the smallest dose and the shortest duration of treatment producing a satisfactory clinical response should be sought. The need for continued treatment should be reassessed periodically.

If signs and symptoms of tardive dyskinesia appear in a patient on antipsychotics, drug discontinuation should be considered. However, some patients may require treatment despite the presence of the syndrome.

(For further information about the description of tardive dyskinesia and its clinical detection, please refer to ADVERSE REACTIONS and PRECAUTIONS–Information for Patients.)

Neuroleptic Malignant Syndrome (NMS) A potentially fatal symptom complex sometimes referred to as Neuroleptic Malignant Syndrome (NMS) has been reported in association with antipsychotic drugs. Clinical manifestations of NMS are hyperpyrexia, muscle rigidity, altered mental status (including catatonic signs) and evidence of autonomic instability (irregular pulse or blood pressure, tachycardia, diaphoresis, and cardiac dysrhythmias). Additional signs may include elevated creatine phosphokinase, myoglobinuria (rhabdomyolysis) and acute renal failure.

The diagnostic evaluation of patients with this syndrome is complicated. In arriving at a diagnosis, it is important to identify cases where the clinical presentation includes both serious medical illness (e.g., pneumonia, systemic infection, etc.) and untreated or inadequately treated extrapyramidal signs and symptoms (EPS). Other important considerations in the differential diagnosis include central anticholinergic toxicity, heat stroke, drug fever and primary central nervous system (CNS) pathology.

The management of NMS should include 1) immediate discontinuation of antipsychotic drugs and other drugs not essential to concurrent therapy, 2) intensive symptomatic treatment and medical monitoring, and 3) treatment of any concomitant serious medical problems for which specific treatments are available. There is no general agreement about specific pharmacological treatment regimens for uncomplicated NMS.

If a patient requires antipsychotic drug treatment after recovery from NMS, the potential reintroduction of drug therapy should be carefully considered. The patient should be carefully monitored, since recurrences of NMS have been reported.

Hyperpyrexia, not associated with the above symptom complex, has been reported with other antipsychotic drugs.

Other Sudden, unexpected deaths have occurred in experimental studies of conditions other than Tourette's Disorder. These deaths occurred while patients were receiving dosages in the range of 1 mg per kg. One possible mechanism for such deaths is prolongation of the QT interval predisposing patients to ventricular arrhythmia. An electrocardiogram should be performed before ORAP treatment is initiated and periodically thereafter, especially during the period of dose adjustment.

ORAP may have a tumorigenic potential. Based on studies conducted in mice, it is known that pimozide can produce a dose related increase in pituitary tumors. The full significance of this finding is not known, but should be taken into consideration in the physician's and patient's decisions to use this drug product. This finding should be given special consideration when the patient is young and chronic use of pimozide is anticipated. (see PRECAUTIONS–Carcinogenesis, Mutagenesis, Impairment of Fertility).

PRECAUTIONS

General ORAP (pimozide) may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as driving a car or operating machinery, especially during the first few days of therapy.

ORAP produces anticholinergic side effects and should be used with caution in individuals whose conditions may be aggravated by anticholinergic activity.

ORAP should be administered cautiously to patients with impairment of liver or kidney function, because it is metabolized by the liver and excreted by the kidneys.

Antipsychotics should be administered with caution to patients receiving anticonvulsant medication, with a history of seizures, or with EEG abnormalities, because they may lower the convulsive threshold. If indicated, adequate anticonvulsant therapy should be maintained concomitantly.

Laboratory Tests An ECG should be done at baseline and periodically thereafter throughout the period of dose adjustment. Any indication of prolongation of QT_c interval beyond an absolute limit of 0.47 seconds (children) or 0.52 seconds (adults), or more than 25% above the patient's original baseline should be considered a basis for stopping further dose increase (see CONTRAINDICATIONS) and considering a lower dose.

Since hypokalemia has been associated with ventricular arrhythmias, potassium insufficiency, secondary to diuretics, diarrhea, or other cause, should be corrected before ORAP therapy is initiated and normal potassium maintained during therapy.

Drug Interactions Because ORAP prolongs the QT interval of the electrocardiogram, an additive effect on QT interval would be anticipated if administered with other drugs, such as phenothiazines, tricyclic antidepressants or antiarrhythmic agents, which prolong the QT interval. Such concomitant administration should not be undertaken (see CONTRAINDICATIONS)

ORAP may be capable of potentiating CNS depressants, including analgesics, sedatives, anxiolytics, and alcohol.

Carcinogenesis, Mutagenesis, Impairment of Fertility Carcinogenicity studies were conducted in mice and rats. In mice, pimozide causes a dose-related increase in pituitary and mammary tumors.

When mice were treated for up to 18 months with pimozide, pituitary gland changes developed in females only. These changes were characterized as hyperplasia at doses approximating the human dose and adenoma at doses about fifteen times the maximum recommended human dose on a mg per kg basis. The mechanism for the induction of pituitary tumors in mice is not known.

Mammary gland tumors in female mice were also increased, but these tumors are expected in rodents treated with antipsychotic drugs which elevate prolactin levels. Chronic administration of an antipsychotic also causes elevated prolactin levels in humans. Tissue culture experiments indicate that approximately one-third of human breast cancers are prolactin-dependent in vitro, a factor of potential importance if the prescription of these drugs is contemplated in a patient with a previously detected breast cancer. Although disturbances such as galactorrhea, amenorrhea, gynecomastia, and impotence have been reported with antipsychotic drugs, the clinical significance of elevated serum prolactin levels is unknown for most patients. Neither clinical studies nor epidemiologic studies conducted to date have shown an association between chronic administration of these drugs and mammary tumorigenesis. The available evidence, however, is considered too limited to be conclusive at this time.

In a 24 month carcinogenicity study in rats, animals received up to 50 times the maximum recommended human dose. No increased incidence of overall tumors or tumors at any site was observed in either sex. Because of the limited number of animals surviving this study, the meaning of these results is unclear.

Pimozide did not have mutagenic activity in the Ames test with four bacterial test strains, in the mouse dominant lethal test or in the micronucleus test in rats.

Reproduction studies in animals were not adequate to assess all aspects of fertility. Nevertheless, female rats administered pimozide had prolonged estrus cycles, an effect also produced by other antipsychotic drugs.

Pregnancy Category C. Reproduction studies performed in rats and rabbits at oral doses up to 8 times the maximum human dose did not reveal evidence of teratogenicity. In the rat, however, this multiple of the human dose resulted in decreased pregnancies and in the retarded development of fetuses. These effects are thought to be due to an inhibition or delay in implantation which is also observed in rodents administered other antipsychotic drugs. In the rabbit, maternal toxicity, mortality, decreased weight gain, and embryotoxicity including increased resorptions were dose related. Because animal reproduction studies are not always predictive of human response, pimozide should be given to a pregnant woman only if the potential benefits of treatment clearly outweigh the potential risks.

Labor and Delivery This drug has no recognized use in labor or delivery.

Nursing Mothers It is not known whether pimozide is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for tumorigenicity and unknown cardiovascular effects in the infant, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use Although Tourette's Disorder most often has its onset between the ages of 2 and 15 years, information on the use and efficacy of ORAP in patients less than 12 years of age is limited.

Because its use and safety have not been evaluated in other childhood disorders, ORAP is not recommended for use in any condition other than Tourette's Disorder.

ADVERSE REACTIONS

General: Extrapyramidal Reactions: Neuromuscular (extrapyramidal) reactions during the administration of ORAP (pimozide) have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved Parkinson-like symptoms which, when first observed, were usually mild to moderately severe and usually reversible.

Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently. Severe extrapyramidal reactions have been reported to occur at relatively low doses. Generally the occurrence and severity of most extrapyramidal symptoms are dose related since they occur at relatively high doses and have been shown to disappear or become less severe when the dose is reduced. Administration of antiparkinson drugs such as benztropine mesylate or trihexyphenidyl hydrochloride may be required for control of such reactions. It should be noted that persistent extrapyramidal reactions have been reported and that the drug may have to be discontinued in such cases.

Withdrawal Emergent Neurological Signs: Generally, patients receiving short term therapy experience no problems with abrupt discontinuation of antipsychotic drugs. However, some patients on maintenance treatment experience transient dyskinetic signs after abrupt withdrawal. In certain of these cases the dyskinetic movements are indistinguishable from the syndrome described below under "Tardive Dyskinesia" except for duration. It is not known whether gradual withdrawal of antipsychotic drugs will reduce the rate of occurrence of withdrawal emergent neurological signs but until further evidence becomes available, it seems reasonable to gradually withdraw use of ORAP.

Tardive Dyskinesia: ORAP may be associated with persistent dyskinesias. Tardive dyskinesia, a syndrome consisting of potentially irreversible, involuntary, dyskinetic movements, may appear in some patients on long-term therapy or may occur after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities and the trunk.

There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, this syndrome may be masked.

It has been reported that fine vermicular movement of the tongue may be an early sign of tardive dyskinesia and if the medication is stopped at that time the syndrome may not develop.

Electrocardiographic Changes: Electrocardiographic changes have been observed in clinical trials of ORAP in Tourette's Disorder and schizophrenia. These have included prolongation of the QT interval, flattening, notching and inversion of the T wave and the appearance of U waves. Sudden, unexpected deaths and grand mal seizure have occurred at doses above 20 mg/day

Neuroleptic Malignant Syndrome: Neuroleptic malignant syndrome (NMS) has been reported with ORAP. (See WARNINGS for further information concerning NMS.)

Hyperpyrexia: Hyperpyrexia has been reported with other antipsychotic drugs.

Clinical Trials The following adverse reaction tabulation was derived from 20 patients in a 6 week long placebo controlled clinical trial of ORAP in Tourette's Disorder.

Body System/ Adverse Reaction	Pimozide (N = 20)	Placebo (N = 20)
Body as a Whole		
Headache	1	2
Gastrointestinal		
Dry mouth	5	1
Diarrhea	1	0
Nausea	0	2
Vomiting	0	1
Constipation	4	2
Eructations	0	1
Thirsty	1	0
Appetite increase	1	0
Endocrine		
Menstrual disorder	0	1
Breast secretions	0	1
Musculoskeletal		
Muscle cramps	0	1
Muscle tightness	3	0
Stooped posture	2	0
CNS		
Drowsiness	7	3
Sedation	14	5
Insomnia	2	2
Dizziness	0	1
Akathisia	8	0
Rigidity	2	0
Speech disorder	2	0
Handwriting change	1	0
Akinesia	8	0
Psychiatric		
Depression	2	3
Excitement	0	1
Nervous	1	0
Adverse behavior effect	5	0
Special Sense		
Visual disturbance	4	0
Taste change	1	0
Sensitivity of eyes to light	1	0
Decreased accommodation	4	1
Spots before eyes	0	1
Urogenital		
Impotence	3	0

Because clinical investigational experience with ORAP in Tourette's Disorder is limited, uncommon adverse reactions may not have been detected. The physician should consider that other adverse reactions associated with antipsychotics may occur.

Other Adverse Reactions In addition to the adverse reactions listed above, those listed below have been reported in U.S. clinical trials of ORAP in conditions other than Tourette's Disorder.

Body as a Whole: Asthenia, chest pain, periorbital edema
Cardiovascular/Respiratory: Postural hypotension, hypotension, hypertension, tachycardia, palpitations
Gastrointestinal: Increased salivation, nausea, vomiting, anorexia, GI distress
Endocrine: Loss of libido
Metabolic/Nutritional: Weight gain, weight loss
Central Nervous System: Dizziness, tremor, parkinsonism, fainting, dyskinesia
Psychiatric: Excitement
Skin: Rash, sweating, skin irritation
Special Senses: Blurred vision, cataracts
Urogenital: Nocturia, urinary frequency

Postmarketing Reports The following experiences were described in spontaneous postmarketing reports. These reports do not provide sufficient information to establish a clear causal relationship with the use of ORAP.

Hematologic: Hemolytic anemia

OVERDOSAGE

In general, the signs and symptoms of overdosage with ORAP (pimozide) would be an exaggeration of known pharmacologic effects and adverse reactions, the most prominent of which would be: 1) electrocardiographic abnormalities, 2) severe extrapyramidal reactions, 3) hypotension, 4) a comatose state with respiratory depression.

In the event of overdosage, gastric lavage, establishment of a patent airway and, if necessary mechanically-assisted respiration are advised. Electrocardiographic monitoring should commence immediately and continue until the ECG parameters are within the normal range. Hypotension and circulatory collapse may be counteracted by use of intravenous fluids, plasma, or concentrated albumin, and vasopressor agents such as metaraminol, phenylephrine and norepinephrine. Epinephrine should not be used. In case of severe extrapyramidal reactions, antiparkinson medication should be administered. Because of the long half-life of pimozide, patients who take an overdose should be observed for at least 4 days. As with all drugs, the physician should consider contacting a poison control center for additional information on the treatment of overdose.

DOSAGE AND ADMINISTRATION

Reliable dose response data for the effects of ORAP (pimozide) on tic manifestations in Tourette's Disorder patients below the age of twelve are not available. Consequently, the suppression of tics by ORAP requires a slow and gradual introduction of the drug. The patient's dose should be carefully adjusted to a point where the suppression of tics and the relief afforded is balanced against the untoward side effects of the drug.

An ECG should be done at baseline and periodically thereafter, especially during the period of dose adjustment (see WARNINGS and PRECAUTIONS–Laboratory Tests).

In general, treatment with ORAP should be initiated with a dose of 1 to 2 mg a day in divided doses. The dose may be increased thereafter every other day. Most patients are maintained at less than 0.2 mg/kg per day, or 10 mg/day, whichever is less. Doses greater than 0.2 mg/kg/day or 10 mg/day are not recommended.

Periodic attempts should be made to reduce the dosage of ORAP to see whether or not tics persist at the level and extent first identified. In attempts to reduce the dosage of ORAP, consideration should be given to the possibility that increases of tic intensity and frequency may represent a transient, withdrawal related phenomenon rather than a return of disease symptoms. Specifically, one to two weeks should be allowed to elapse before one concludes that an increase in tic manifestations is a function of the underlying disease syndrome rather than a response to drug withdrawal. A gradual withdrawal is recommended in any case.

HOW SUPPLIED

ORAP (pimozide) 2 mg tablets, white, scored, imprint "LEMMON" and "ORAP-2"—NDC 57844-187-01, bottles of 100.

Dispense in tight, light-resistant containers as defined in the official compendium.

Cerebral Structure on Magnetic Resonance Imaging in Language- and Learning-Impaired Children

Terry L. Jernigan, PhD; John R. Hesselink, MD; Elizabeth Sowell; Paula A. Tallal, PhD

• Using magnetic resonance imaging 20 language- and learning-impaired children were compared with 12 normal control subjects. Gross brain structure was remarkably normal in the language- and learning-impaired group. Semiautomated morphometry was used to measure hemispheric volumes and cerebral asymmetries in six cerebral regions. The volume of the left posterior perisylvian region was significantly reduced in language- and learning-impaired children. Asymmetries in inferoanterior and superoposterior cerebral regions were also significantly different in this group. Results of descriptive group comparisons of estimated volumes of other cerebral gray-matter structures raise the possibility that some language- and learning-impaired children may have additional volume reductions in cortical and subcortical structures. The results suggest that hemispheric specialization of function may be anomalous in this population.

(*Arch Neurol.* 1991;48:539-545)

Developmental dysphasia is a specific disorder of language development of unknown etiology.[1] Because the disorder is not life-threatening, neuropathological examinations have been reported in only a few cases.[2,3] Neuropathological studies of dyslexia, a closely related developmental disorder of reading,[4,5] have led to hypotheses about its pathogenesis.[6] Symmetry of the planum temporale of the posterotemporal lobe, an unusual finding in normal subjects, was noted in all dyslexic patients examined in these studies. Also observed were frequent ectopias and dysplasias of the cortex. The planum symmetry appeared to be associated with larger right plana, rather than smaller left plana. It was hypothesized that injury to the brain during corticogenesis may lead to enhanced survival of right planum neurons, which produces anatomical symmetry and altered cerebral dominance.

With the recent advent of noninvasive, in vivo brain imaging methods, a few studies of dyslexia have been reported[7-10] (reviewed by Hynd and Semrud-Clikeman[11]). These imaging studies, employing several different measurement techniques, generally support neuropathological findings of unusual patterns of hemispheric asymmetry in dyslexic subjects. Of the new imaging techniques, magnetic resonance imaging (MRI) offers the most sensitive, noninvasive method for assessing brain structure during life and, as such, provides an unique opportunity for examining brain structure in children with specific developmental language disabilities.

In this study, MRI images from 20 language- and learning-impaired (L/LI) children and 12 matched control subjects were analyzed with semiautomated brain morphometry. Estimated volumes were obtained of cerebral regions and individual gray-matter structures. Based on previous findings with dyslexic children, specific analyses were developed to determine whether L/LI children would show anomalous asymmetries relative to controls.

SUBJECTS AND METHODS

The sample studied was drawn from a larger sample of 95 specifically language-impaired children and 60 age-, IQ-, race-, and socioeconomic status–matched controls, identified at the age of 4 years and studied longitudinally until the age of 8 years. Inclusion in the longitudinal study at the age of 4 years was based on the following criteria for both groups: (1) performance IQ of 85 or greater; (2) normal hearing acuity, no motor handicaps, and no oral, structural, or motor impairments affecting nonspeech movement of the articulators; (3) an English language background without significant dialectical or language differences in the home environment; (4) no obvious signs of infantile autism (as defined by *Diagnostic and Statistical Manual of Mental Disorders, Third Edition*[12]); and (5) no known neurological disorders. Language-impaired children were at least 1 year behind chronological and nonverbal mental age on a battery of standardized receptive and expressive language measures. Normal control children met the same criteria as the language-impaired subjects except that their speech and language skills had to be within 6 months of their chronological age.

A subset of children who completed all 5 years of testing in the longitudinal study were selected to participate in this study. Twenty-eight children who continued to demonstrate significant language impairment as well as academic achievement deficits were selected as L/LI subjects. These subjects were selected initially based on their language impairment at the age of 4 years. At the time of this imaging study, when they had an average age of 9 years, they continued to be language impaired, but in addition, many had severe learning disabilities that emerged during the longitudinal study. For this reason, these subjects have been classified as L/LI. They may or may not be the same as those children selected based solely on reading ability (ie, developmental dyslexics), although they all did have severe reading impairment when MRI scanning was performed. Fourteen matched controls who demonstrated normal language development and academic achievement (reading, spelling, and mathematics) also agreed to participate.

Eight of the L/LI children and two of the controls were unable to complete the procedure, or the magnetic resonance images were

technically inadequate for analysis owing to motion artifact. Thus, 20 L/LI children (13 boys and seven girls) and 12 control children (eight boys and four girls), aged 8 to 10 years, were studied. Table 1 summarizes the subjects' characteristics. The groups remained well matched for age and sex; however, the controls had a somewhat higher mean performance IQ. Seventeen of the L/LI children had Wechsler Intelligence Scale for Children performance IQs greater than 80. The remaining three had performance IQs of 75, 73, and 64 (demonstrating a decrease from their previous performance IQs as measured at the age of 4 years). Also, at the time of MRI scanning, all L/LI children lagged 2 years behind chronological age on the Curtiss-Yamada Comprehensive Language Evaluation Expressive or Receptive scales, except for one child who lagged 1 year behind on both scales, but had mathematics and vocabulary percentile scores of 0.

All but three children (two L/LI, one control) were right-handed. Because of concern about altered cerebral organization and symmetry in the left-handers, all analyses were conducted with and without these subjects. Both sets of results are given below, although they were virtually identical.

Table 1.—Subject Characteristics*

	Control	L/LI
No. of subjects	12 (11)	20 (18)
Sex, F/M	4/8 (3/8)	7/13 (6/12)
Handedness, L/R	1/11 (11)	2/18 (18)
Age, y, mean ± SD	9.0 ± 0.7 (8.9 ± 0.7)	8.9 ± 0.7 (9.0 ± 0.7)
WISC PIQ, mean ± SD	109 ± 14 (110 ± 14)	97 ± 16 (98 ± 16)
CYCLE age levels, mean ± SD		
Expressive	8.3 ± 1.4 (8.2 ± 1.5)	4.8 ± 1.2 (4.7 ± 1.3)
Receptive	8.3 ± 1.0 (8.4 ± 0.9)	5.3 ± 1.4 (5.3 ± 1.4)

*Results omitting left-handed subjects are given in parentheses. L/LI indicates language and learning impaired; WISC PIQ, Wechsler Intelligence Scale for Children Performance IQ; and CYCLE, Curtiss-Yamada Comprehensive Language Evaluation. CYCLE age levels are equivalents at 8-year-old testing. One L/LI subject who did not complete the WISC testing is omitted from the calculation of PIQ; his Leiter IQ was 118 less than 1 year before scanning.

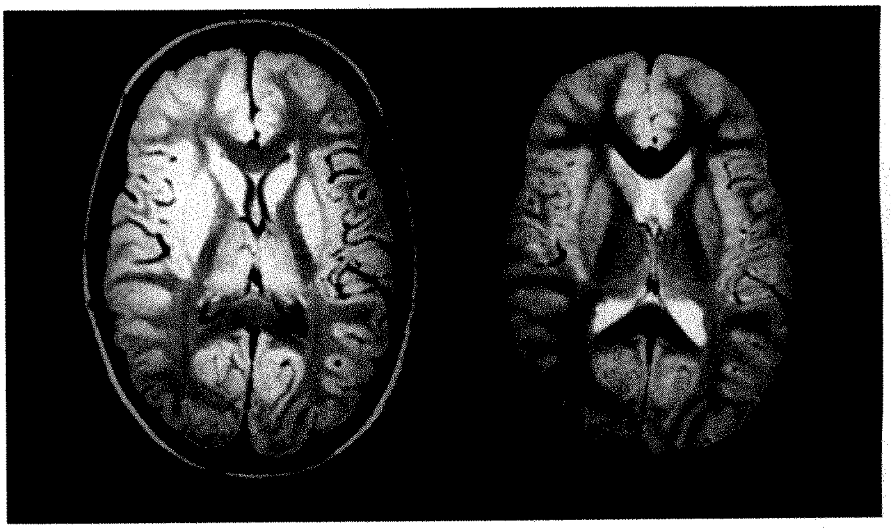

Fig 1.—Representative images from the standard protocol. Left, Repetition time, 2000 milliseconds; echo time, 25 milliseconds (proton density–weighted in text). Right, Repetition time, 2000 milliseconds; echo time, 70 milliseconds (T_2-weighted in text). Sections are 5 mm thick, with 2.5-mm gaps between images. A 24-cm field of view was used, and the matrix was 256 × 256.

MRI Protocol

Magnetic resonance imaging was performed with a 1.5-T superconducting magnet (Signa; General Electric, Milwaukee, Wis) at the University of California, San Diego/AMI Magnetic Resonance Institute. Proton density–weighted and T_2-weighted images (Fig 1) were obtained simultaneously for each section, using an asymmetrical, multiple-echo sequence (repetition time, 2000 milliseconds; echo time, 25, 70 milliseconds) to obtain images of the entire brain in the axial plane. Section thickness was 5 mm, with a 2.5-mm gap between successive sections in all instances. A 256 × 256 matrix and 24-cm field of view were used. Thus, a voxel measured $0.9375 \times 0.9375 \times 5$ mm, subtending a volume of 4.39 mm^3. No sedation was used during these examinations. Informed consent and full cooperation were obtained from all of the children and their parents.

MRI Analysis

The primary goal of the image-analytic methods was to define a region that would include those posterior perisylvian cortical structures of the temporal and parietal lobes that were deemed most relevant for the affected language functions, and to ensure that this region would have consistent boundaries from one subject to the next. Of secondary interest were other regions, including such cortical structures as the anterior language areas in insular cortex and superior parietal association cortex. Finally, for the purpose of exploratory analyses, major subcortical structures were also examined.

The visual identification of specific structures in magnetic resonance images is possible because of the tissue contrast between the gray-matter structures and the surrounding white matter or cerebrospinal fluid (CSF). However, measurements of volumes of cerebral structures must overcome several problems. First, because of partial voluming of gray matter, white matter, and CSF (or all three) at the edges of structures, definite edges are not always present. This allows considerable scope for variability in subjective determinations of such boundaries, for example, when tracing methods are used, leading to measurement unreliability in the computed volumes.

Visual determination of specific cortical structures on MRI depends on the presence of visible gross structural features relative to which the boundaries of the cortical regions can be defined. Standard regional divisions for the cortex are largely based on cortical gyral patterns, but the accurate localization of particular gyri or sulci, throughout a series of images, is often impossible. Furthermore, some boundaries, such as that between posterotemporal and inferoparietal cortex, are not clearly defined in gross structural terms (Fig 2). Also, even when attempts are made to standardize head positioning, head rotation (relative to the imaging plane) occurs in all three planes. This is especially true with unsedated subjects who must be sufficiently comfortable in position to avoid movement during the imaging session. Careful inspection indicates that small rotations substantially change the appearance of brain structures in the image plane, further complicating their visual identification; in addition, such rotations lead to spurious within-plane asymmetries of apparently comparable structures in the two hemispheres. Thus, manually tracing the structures in the sections where they are best visualized often leads to inaccurate volume and asymmetry assessments. The following techniques are designed to address each of these difficulties.

To facilitate and standardize the determination of structural edges, the present method involves a semiautomated classification of all pixels in the images based on their signal characteristics on the two original images of each section. A detailed description of the basic image analysis method has been reported elsewhere.[13] Only a brief summary is provided herein. For each axial brain section imaged, a computed matrix is produced. In this matrix, voxels are classified as most resembling (in signal strength) gray matter, white matter, CSF, or signal hyperintensities (tissue abnormalities). The full series of axial images is analyzed, beginning at the

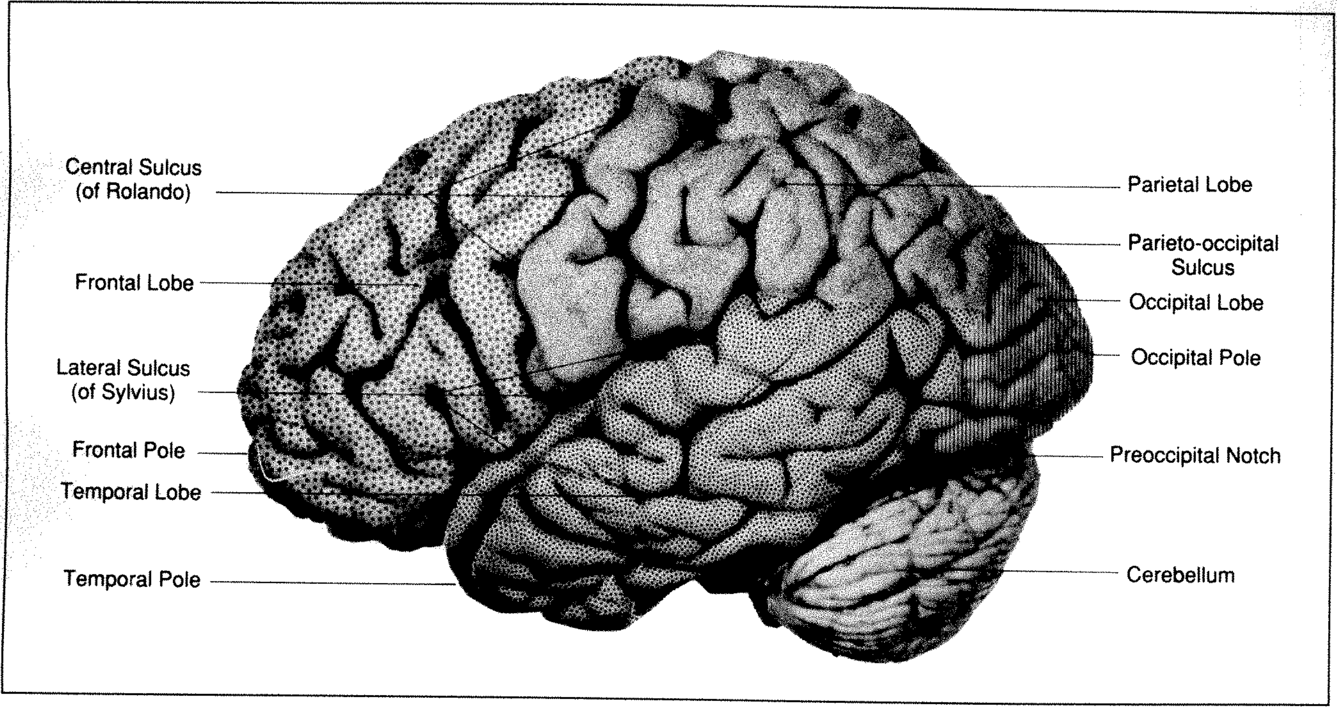

Fig 2.—The lateral surface of the brain (from Montemurro and Bruni[23]). The primary lobes of the cortex are designated by stippling. Gross structural features such as the fissure of Rolando and the sylvian fissure provide partial lobar boundaries on the cortical surface. However, no gross anatomical landmarks are present on the surface of the posterotemporal and inferoparietal lobes to define their boundary, and a somewhat arbitrary line is drawn. The anterior border of the occipital lobe also lacks surface landmarks for precise localization.

bottom of the cerebellar hemispheres and extending through the vertex.

Further manipulations to derive the measures for this study were then made by trained operators, who were "blind" to subject age or group status, using a stylus-controlled cursor on the displayed "pixel-classified" images.

Definition of Subcortical Structures

To delineate subcortical structures, the operators circumscribed pixels classified as gray matter that were visually determined to be in caudate nuclei, lenticular nuclei, and diencephalic gray-matter structures (including mammillary bodies, hypothalamic gray matter, septal nuclei, and thalamus). They did not trace the edges of the structures but defined polygons that included all gray-matter pixels within the structures, and excluded those gray-matter pixels associated with other structures. In some cases, when the subcortical nuclei were contiguous with other areas classified as gray matter but clearly not in the structures, boundaries were manually constructed.

Definition of Cerebral Regions

To define anatomically consistent cerebral regions, a method was adopted for making subdivisions of the cerebrum relative to the centromedial structural midline and two consistently identifiable points: the most anterior midline point in the genu and the most posterior midline point in the splenium of the corpus callosum. By calculating rotation angles using these landmarks, a three-dimensional rotation of the images was performed, thus correcting each individual's image data for rotation out of the optimal imaging plane. Regions could then be constructed that resulted in highly consistent placement of regional boundaries relative to gross anatomical landmarks.

The orientation of the midsagittal plane was first determined by computing a regression line through a series of visually selected brain-stem midline points. The division of the cerebrum was then based on two major planes (Fig 3): an axial plane, which is perpendicular in orientation to the midsagittal plane and parallel to the plane passing through the two corpus callosum points, and a coronal plane, which is defined as perpendicular to the first plane and which passes through the midpoint between the two corpus callosum points. The placement of the axial plane was standardized to the maximum z axis extent of the cerebrum, at 64% of the distance from the bottom of the cerebrum. This distance was chosen because it consistently reached the top of the highest of the two sylvian fissures in a group of eight subjects.

By computing new coordinates for each voxel relative to these planes, each is assigned to one of four zones: one, inferior to the axial plane and anterior to the coronal plane (IA); two, inferior to the axial plane and posterior to the coronal plane (IP); three, superior to the axial plane and anterior to the coronal plane (SA); and four, superior to the axial plane and posterior to the coronal plane (SP). Again, these defined planes are independent of the image plane, as a three-dimensional rotation is first applied based on the positions of the landmarks described earlier. This division resulted in the inclusion of all posterior perisylvian cortical structures in the IP zone; however, the occipital lobe was also included in this zone. Similarly, the IA zone included anterotemporal and frontal cortical structures.

To separate occipital from temporoparietal areas in the IP zone, and prefrontal from anterotemporal areas in the IA zone, two additional coronal dividing planes were defined. In the IA zone, a plane was defined that was parallel to the central plane and passed through the midline genu point. Similarly, in the IP zone, a plane was defined that was parallel to the central plane and that was positioned along the centromedial midline at a distance that consistently fell near the parieto-occipital sulcus. Thus, the two inferior zones were subdivided into four zones, described in gross terms as follows: the first (IA1), the most anterior, included prefrontal cortex; the second (IA2) included anterotemporal and anterior insular cortex; the third (IP1) included posterotemporal, posterior insular, and perisylvian parietal cortex; and the fourth (IP2), the most posterior, included mostly occipital and some posterotemporal cortex on the lateral surface. Figures 3 and 4 illustrate the location of the six cerebral zones defined by these planes. The division of brain structures into the zones is summarized in Table 2.

The regional boundaries are defined relative to the corpus callosum landmarks and the midsagittal plane. Therefore, they do not represent precisely defined neuroanatomical regions. Nevertheless, remarkable consistency in the placement of the boundaries, relative to all recognizable gross features, was observed. Regional maps, such as that seen in Fig 4, were generated for each subject in the study, and each was inspected to

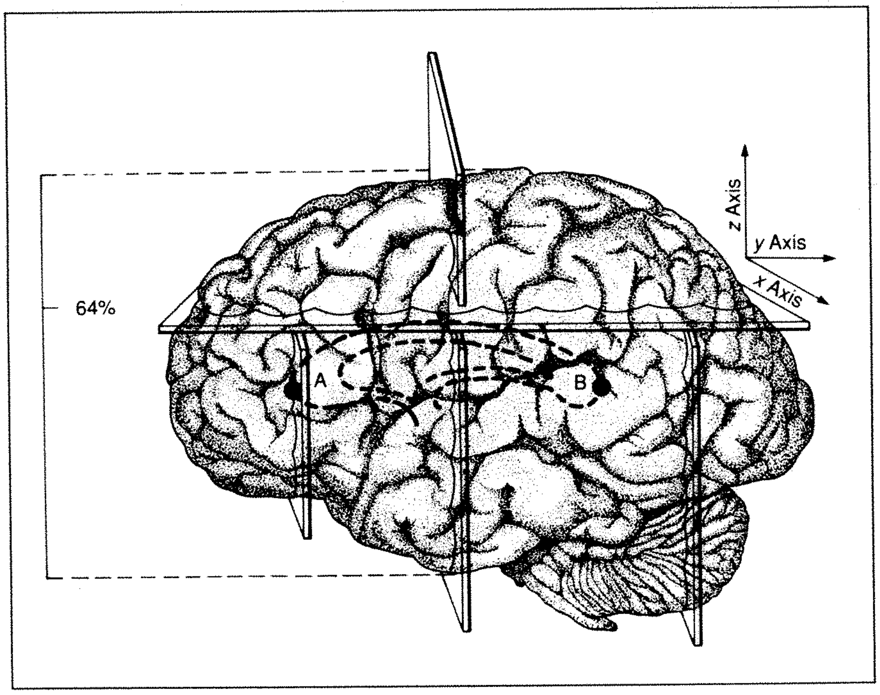

Fig 3.—Cerebral regions are defined as follows. Points A and B in the corpus callosum are the most anterior midline point in the genu and the most posterior midline point in the splenium, respectively. An axial plane, parallel to the plane passing through these two points, is defined as shown, perpendicular to the midsagittal plane. This plane is placed 64% of the distance from the bottom to the top of the supratentorial cranial vault. A coronal plane is defined perpendicular to the axial plane and passing through the midpoint between points A and B. Within the region below the axial dividing plane, two further (parallel) coronal dividing planes are defined, one passing through the genu midline point and one passing through the parieto-occipital sulcus. Thus, six cerebral zones are defined: inferoanterior 1, inferoanterior 2, inferoposterior 1, inferoposterior 2, superoanterior, and superoposterior.

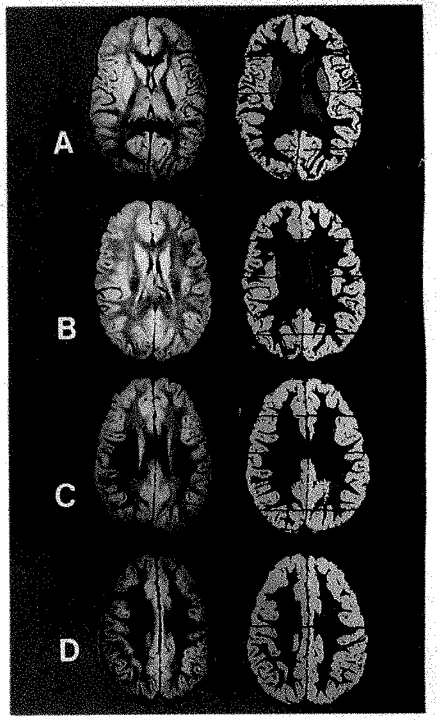

Fig 4.—Representative, fully processed images displayed adjacent to the original proton density–weighted images. Pixels are classified, and zones have been manually designated. The gray-matter pixels have been color coded to display the structural designations: right hemisphere cortical is yellow; left hemisphere cortical, white; caudate, blue; lenticular nucleus, pink; and diencephalon, green. Hyperintense areas within the subcortical regions are shown in gray. Cerebrospinal fluid and white-matter pixels in all regions are displayed in red and black, respectively; however, these pixels are coded so that regional measures may be computed. Sections in A through C are entirely inferior to the axial dividing plane. The section in D is completely superior to the dividing plane. For inferior and superior zones, the central line indicates the position of the major coronal dividing plane. In the inferior zone, two additional lines indicate the positions of the two secondary coronal dividing planes.

ensure that the regions did not vary discernibly in terms of the structures included. In all cases, the inferior zone extended to the highest point in the sylvian fissure that could be recognized in the images. From inspection of the images, Table 2 was compiled to assist in the interpretation of the results. It is not meant to convey the impression that precise boundaries were defined between the structures mentioned.

The total number of supratentorial voxels (including CSF, hyperintensities, and gray and white matter) was computed, by hemisphere, for each of the six zones. Cerebral asymmetry of each of the zones was expressed as a ratio of the left hemisphere measure to its right hemisphere counterpart. Thus, when the left region was larger than the right, the ratio was greater than 1. Volumes of the subcortical gray-matter structures were estimated by summing the appropriate voxels in each hemisphere. All volume estimates are given as simple totals of designated voxels. As described above, each voxel is 4.39 mm^3. However, an estimate of true volume should probably treat the 5-mm sections as representative of the 7.5-mm interslice distance; thus, each voxel would represent 6.49 mm^3. Areas within the lenticular nucleus containing significant iron deposits, particularly in the globus pallidus, do not meet the signal criteria for gray matter and are thus excluded from this region.

A comparison of the original proton density–weighted images and the fully processed images is illustrated in Fig 4. In this figure, the different pixel classes are color coded as follows: right hemisphere cortical gray matter is yellow; left hemisphere cortical gray matter, white; diencephalic areas, green; caudate nuclei, blue; lenticular nuclei, pink; and fluid and white matter, red and black, respectively. Pixels in the subcortical region shown in gray are areas within white matter or surrounding the ventricles that have higher T_2 values than other white matter regions. The blue lines running through the sections indicate the positions of the coronal dividing planes. For this set of images, the boundary between the inferior and superior zones fell between sections C and D.

Statistical Analyses

Group means for the measures were compared with Student's *t* tests. The comparisons of the six asymmetry measures test the hypothesis that cerebral development is anomalous in the L/LI children. Because of multiple asymmetry comparisons, $P<.01$ was required to reject the null hypothesis. The other comparisons are provided for descriptive purposes only. The meaning of statistical significance of individual test statistics in the context of multiple tests is ambiguous, and probabilities are provided for the secondary comparisons only to aid in interpretation of patterns. Inferences about structural abnormalities from these post hoc comparisons must be made with caution.

RESULTS

On routine clinical neuroradiological evaluation, 16 of 20 examinations in the L/LI children were unremarkable. Slight asymmetry of the ventricles (right larger) was noted in one male subject. One boy and one girl had tiny foci of hyperintensity in deep white matter. In one male participant, bilateral areas of encephalomalacia were present just lateral to the caudate nuclei, with the larger right lesion measuring 8 mm in width.

Among the control children, eight of 12 examinations were unremarkable. Tiny foci of hyperintensity were noted in one boy and one girl. A right cerebellar venous angioma was noted in one boy. A small pituitary gland was noted

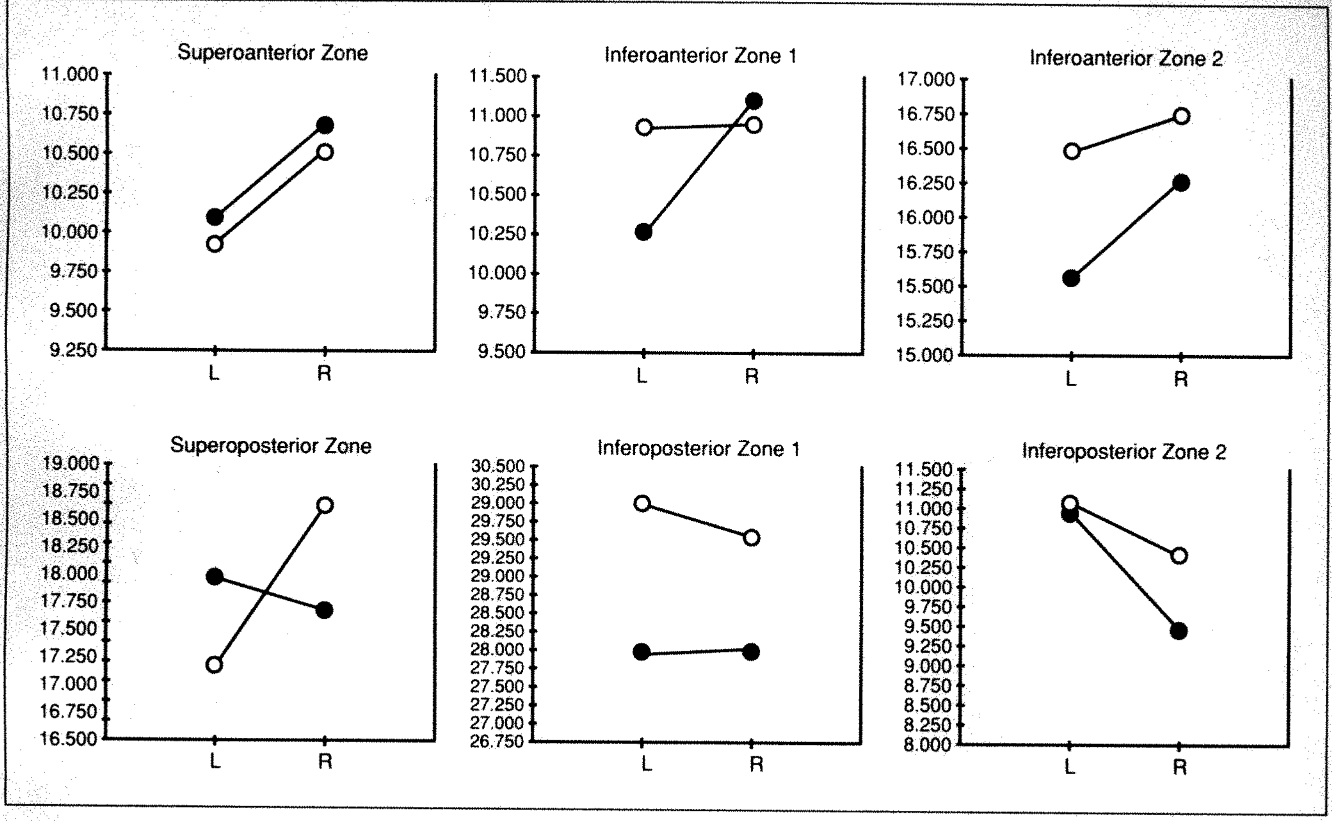

Fig 5.—Mean estimated volumes in thousands of voxels are plotted for each hemisphere by cerebral region. Open circles denote control values; closed circles, values from learning- and language-impaired subjects. All subjects, including left-handers, are included.

Table 2.—Summary of Cortical Structures Within Each Cerebral Region

- **Inferoanterior 1**
  - Prefrontal cortex inferior to plane above frontal operculum, including orbitofrontal, dorsolateral, and mesial frontal lobe
- Inferoanterior 2 (IA2)
  - Temporal poles, uncus, and some amygdala; anterior perforated substance and adjacent orbitofrontal cortex; anterior insular cortex and frontal operculum
- Inferoposterior 1
  - Most of temporal lobe, including all mesial temporal lobe structures posterior to amygdala (only temporal pole is included in IA2); perisylvian parietal cortex and parietal operculum
- Inferoposterior 2
  - Most of occipital lobe (only small portion of superior occipital cortex is included in SP); small part of most posterior gyri of temporal lobe on lateral cortical surface
- Superoanterior
  - Superior parts of dorsolateral and mesial frontal lobes (above frontal operculum)
- Superoposterior (SP)
  - Superoparietal lobe above parietal operculum; small portion of most superior occipital lobe

Table 3.—Group Differences on Cerebral Asymmetries*

Region	Ratios (L/R) Controls	Ratios (L/R) L/LI	*t*	*P*
IA1	1.00 ± 0.04 (1.00 ± 0.04)	0.92 ± 0.07 (0.93 ± 0.06)	3.68 (3.12)	.001 (.004)
IA2	0.99 ± 0.04 (0.98 ± 0.04)	0.96 ± 0.05 (0.97 ± 0.04)	1.66 (1.10)	.107 (.280)
IP1	1.02 ± 0.03 (1.01 ± 0.03)	1.00 ± 0.05 (1.01 ± 0.04)	0.97 (0.30)	.339 (.764)
IP2	1.06 ± 0.10 (1.06 ± 0.10)	1.17 ± 0.16 (1.17 ± 0.16)	2.12 (2.15)	.043 (.041)
SA	0.95 ± 0.10 (0.96 ± 0.09)	0.95 ± 0.07 (0.94 ± 0.06)	0.11 (0.68)	.913 (.503)
SP	0.93 ± 0.07 (0.93 ± 0.08)	1.02 ± 0.08 (1.01 ± 0.07)	3.17 (2.79)	.003 (.010)

*Values are mean ± SD. Results omitting left-handed subjects are given in parentheses. L/LI indicates language and learning impaired; IA1 and IA2, inferoanterior 1 and 2; IP1 and IP2, inferoposterior 1 and 2; SA, superoanterior; and SP, superoposterior.

in another boy. Thus, incidental findings on routine clinical evaluation of the images did not reveal consistent parenchymal or structural differences between the groups.

Group comparisons of cerebral asymmetries in the six regions are summarized in Table 3. The pattern observed only in right-handed subjects is the same as that observed in the full sample. Both IA1 and SP asymmetries are significantly different in the L/LI group ($P<.01$ in each case). The ratio is significantly decreased in the IA1 region and significantly increased in the SP region. An illustration of the different patterns of asymmetry (for the full sample) is provided in Fig 5, showing group mean volumes for the right and left hemispheres within each region. In the normal controls, the IA1 regions are symmetrical, while in the L/LI children, the left hemisphere is reduced relative to the right. For the SP region, the normal controls show right-larger asymmetry, while an opposite pattern is observed in the L/LI subjects.

Secondary analyses focused on the hemispheric volumes of the cerebral (cranial) regions and the subcortical nu-

Table 4.—Group Differences in Cerebral Volumes*

*Results omitting left-handed subjects are given in parentheses. Abbreviations are as in Table 3.

Table 5.—Asymmetries in Posterior Perisylvian Region*

	Hemisphere Symmetry (L:R Ratio)		
	R > L (≤0.99)	Symmetrical (0.99-1.01)	L > R (≥1.01)
Controls	1 (1)	4 (4)	7 (6)
L/LI	10 (8)	1 (1)	9 (9)

*Results omitting left-handed subjects are given in parentheses. L/LI indicates language and learning impaired. For total group, Pearson $\chi^2 = 7.9$, $df = 2$, $P = .019$; for group omitting left-handed subjects, Pearson $\chi^2 = 6.5$, $df = 2$, $P = .038$.

clei. Table 4 summarizes group comparisons of these measures. Although many mean volumes are lower in the L/LI group, when examining the full sample, of the cerebral region measures, that in the left IP1 region (posterior perisylvian) is particularly reduced in the L/LI group. Among the subcortical structures, only the right diencephalic volume is notably reduced, although the right caudate measure is also low. The exclusion of left-handers resulted in somewhat larger group differences on these measures, so that left and right IP1 regions appear to be reduced, as is right IP2, and the caudate reductions are slightly more prominent. Though they are not presented herein, no left-right asymmetry in the subcortical volumes yielded a group difference with $P<.05$. Also, because cortical gray-matter volumes were available for right and left hemisphere of each of the six regions, regional cortical asymmetry measures were computed. The pattern of group differences was the same as that for the cranial regions, with significant differences in regions IA1 and SP.

Because earlier studies have classified subjects categorically based on their posterior asymmetries, we examined our data for evidence that the mean asymmetries may have obscured differences in distribution. Indeed, the variance for the asymmetry measures in region IP1 was significantly larger in the L/LI sample than in the control sample ($P<.05$). Therefore, a post hoc frequencies analysis was performed. Table 5 gives the asymmetries in categorical form. The L/LI group did have a somewhat higher prevalence of reversed asymmetries. A χ^2 statistic suggested that the distributions were indeed different; however, the small frequencies in some cells render the statistical test suspect.

Measures of ventricular and sulcal size, as well as proportions of gray to white matter, were similar in the two groups, as assessed with quantitative methods. Furthermore, there was no evidence for abnormal signal values in the white matter in the L/LI children as a group. In summary, there was no evidence from the group comparisons for significant damage to or loss of tissue in the form of increased CSF or hyperintense white matter areas.

COMMENT

The pattern observed in the control subjects of this study suggests that within hemispheres roughly equal in size overall, significant regional asymmetries do occur, with posterior structures larger on the left in inferior and larger on the right in superior zones. In frontal areas, the volumes are symmetrical in the inferior zone, and the right hemisphere volume is larger in the superior zone. The posterior asymmetries seem to be consistent with left hemisphere specialization for language in the posterior temporal lobes and right hemisphere specialization for spatial functions in the parietal lobes. Furthermore, these asymmetries, as well as the frontal asymmetry in the superior zone, are consistent with earlier reports of regional asymmetries in normal subjects.[14-21]

Regarding the absolute values obtained on the asymmetry measures, a caveat should be entered about possible spatial distortion due to field inhomogeneity.[22] Thus, although these results suggest that in both groups the hemispheres are nearly the same size, ie, the left-right ratio has a mean of 0.99 in controls and 1.00 in L/LI children, one or both of the hemispheres may have been systematically measured inaccurately owing to magnification or minification in some parts of the magnetic field. Nevertheless, such factors should have affected both groups similarly.

The L/LI children in this study were selected at 4 years of age because of specific developmental delays in language function in the context of preserved sensory, motor, and nonverbal intellectual capacities. After 5 years of study, at 9 years of age, they have continuing significant, in some cases severe, language and learning impairment. Gross brain structure was remarkably normal in this group of children. There was little evidence for parenchymal damage or volume loss, except in one case. There is definite evidence, however, for anomalous brain development in the form of altered cerebral shape. The L/LI children show abnormal asymmetry, but it does not appear in the posterior perisylvian regions, where it was expected. Rather, these children show an aberrant (right greater than left) asymmetry in the prefrontal region, and an aberrant (left greater than right) asymmetry in the parietal region. Closer inspection of the posterior perisylvian measures, however, reveals a possible explanation for this surprising result. There is evidence from the secondary analyses that this region of the left hemisphere is reduced in volume. Even when this regional volume is expressed as a percentage of the overall supratentorial volume (sum of the regions), it still shows evidence of a proportional decrease in the L/LI children relative to the controls ($P<.05$). However, inspection of the comparable right hemisphere volume also suggests reduction. Thus, the asymmetry is only slightly affected in this region by the (probably bilateral) volume reduction.

Some earlier imaging studies of developmental language disorders[7,8] have produced evidence of an increased prevalence of reversed asymmetry in posterior hemispheric regions. Such studies generally group the subjects in terms of the direction of their asymmetries. To address these findings directly, we conducted post hoc analyses of the distribution of our posterior perisylvian asymmetries. There was weak statistical evidence that more of the L/LI children showed reversed asymmetry (right greater than left). It, therefore, seems prudent to point out that our results should not be interpreted as refuting the earlier findings and, indeed, they provide some supportive evidence for the presence of more frequent reversals in this region.

The question arises whether the findings in these children are similar to neuropathological results in dyslexic children,[4,5] and whether the anomalous asymmetries in this study could have occurred as a result of the mechanisms hypothesized to account for dyslexia.[6] The planum temporale was not specifically examined in this study, owing to the difficulty of reliably determining its boundaries. Thus, the results do not bear directly on the pathological study results. This structure did always fall within the much larger posterior perisylvian region (IP1), where, although the L/LI children showed more variable asymmetries, no significant mean asymmetry difference was found. The pattern observed in this region might appear to be inconsistent with the reported increase in the size of the right planum in dyslexia. The structures in IP1, including the planum but many others as well, are reduced in volume on the left and are nearly as reduced on the right, relative to controls. Similarly, examination of the pattern within the prefrontal region (IA1), where the L/LI children show greater (right greater than left) asymmetry, suggests that the aberration is more likely to be due to reduction of left structures than to preservation of right structures. In the parietal (SP) region, where the L/LI group shows a reversal of the normal (right greater than left) asymmetry, the right hemisphere is smaller in volume in the L/LI group, while the left is larger, although neither difference is itself statistically significant.

Galaburda and colleagues[4-6] found no evidence for a reduction in neuronal populations in the brains of their dyslexic subjects. Rather, they found evidence for disordered migration and possibly enhanced survival of neurons in critical nondominant hemisphere structures. The subjects examined herein may not be representative of the same population. Although many of them are dyslexic, they were not chosen for isolated reading disorders. Longitudinal study of these children suggests more pervasive linguistic and academic limitations, and evidence indicates that in some children overall intellectual abilities have lagged further and further behind peer standards with increasing age. It is possible that the subjects examined herein suffered effects on neurodevelopment at an earlier stage of neurogenesis, leading to reduced cell populations in critical perisylvian structures (hence, the early prominence of their language disturbances) and ultimately to altered cerebral shape. Interestingly, reduced neuronal populations in left hemisphere insular cortex were noted in one neuropathological study of developmental dysphasia.[3] Even if this explanation is correct, it is still unclear whether the shape alterations observed herein are entirely due to decreased volume of certain affected structures, or if they evolve as early alterations, or exert later effects on mechanisms of cortical maturation and specialization such as those proposed by Galaburda.[6] It is even possible that neuronal loss in related structures may have led to altered maturation of the plana in the subjects of the present study, such that enlarged right plana are present within perisylvian regions that are themselves reduced in volume overall. Perhaps further neuropathological studies in a broader range of developmental disorders may shed some light on these questions.

This study confirms that anomalous neurodevelopment in this disorder does produce structural aberration at a level measurable with in vivo brain imaging. The correlation of such measurements with specific behavioral indices, as development proceeds, may provide some insight into the brain mechanisms involved in developmental cognitive disorders.

Allochiria vs *Allesthesia*

Is There a Misperception?

Kimford J. Meador, MD; Martha E. Allen, MD; Robert J. Adams, MD; David W. Loring, PhD

• Allochiria is the mislocation of sensory stimuli to the corresponding opposite half of the body or space. Obersteiner (1882) introduced the term *allochiria* (Greek *allos* = other + *chiria* = hand), and more than 20 authors employed it in this context over the next 25 years. Stewart (1894) described a related phenomenon in which stimuli are displaced to a different point on the same extremity. He noted that the displacements were different than allochiria and coined the term *allachaesthesia* (ie, *allesthesia*) (Greek *allaché* = elsewhere + *aisthésis* = perception). Despite this historical background, Jones (1907) redefined both terms in an attempt to increase diagnostic specificity and attributed allochiria to hysteria. Jones' reinterpretation does not appear to be justified historically, etymologically, or scientifically and has resulted in contradictory definitions of *allochiria* and *allesthesia* in present-day medical dictionaries and neurologic textbooks. We advocate a return to usage consistent with the original descriptions and word derivations.

(*Arch Neurol.* 1991;48:546-549)

The purpose of our article is to delineate the origins and historical development of the terms *allochiria* and *allesthesia*. The account is of interest not only from a historical perspective, but also because of the present confusion in terminology. For example, a review of seven current medical dictionaries[1-7] reveals numerous inconsistencies. First, a variety of orthographic representations are available. Allochiria is listed as *allochiria* (the original) or *allocheiria*. Allesthesia is listed as *allachaesthesia* (the original), *allesthesia, allachesthesia, allaesthesia, allochaesthesia, allochesthesia,* or *alloesthesia*. Second, and more important, a variety of denotations are offered that are inconsistent across, and even within, texts (Table 1). Ignoring the various orthographic differences, allochiria and allesthesia are given different definitions in two dictionaries, only allochiria is listed in one dictionary, and four dictionaries list allochiria and allesthesia as synonymous terms, although one of these dictionaries does give a different definition to one orthographic form of allesthesia (ie, *allachesthesia*), even though the same Greek roots are listed. Textbooks of neurology[8-11] exhibit no better consistency (Table 2). Such diversity does not reflect specific scientific terminology. How is it then that we have come to such a state of confusion?

In 1882, the famous Austrian neuropathologist and neuroanatomist Heinrich Obersteiner founded the Neurologische Institut at the University of Vienna. In that same year, he published an article in *Brain*,[12] in which he introduced the term *allochiria* from the Greek roots *ἄλλοζ* (other) and *χείρ* (hand) to denote a "confusion of sides" seen in patients during tactile stimulation. Obersteiner stated,[12]

> This symptom is so easy to determine that no long description is required. When we test the sensibility of a patient, on the leg for example, and find that the two points of the aesthesiometer are recognized as such at a moderate distance apart, or when a prick or pressure is fairly localised, and yet, as frequently occurs, the irritation is referred to the other side, we have the condition before us. The power of localisation is retained as to details, while doubt or error exists as to the side touched, the irritation being commonly referred to the corresponding part of the other limb. I believe that the phenomenon is less rare than overlooked, as errors on the part of the patient are apt to be regarded as merely a *lapsus verbi*. In the case of intelligent patients, however, and with due care, it soon becomes apparent that this is not the true explanation.

Obersteiner described four cases in detail, including three patients with myelopathy (one traumatic and two tabetic) and one case of presumed hysteria.[12] In addition, he reviewed six cases of tabes from the literature reported by Fischer (1880), Hertzberg (1875), and Von Leyden (1863) in which similar symptomatology had been described but only attributed to a generalized disorder of sensory localization. In contrast, Obersteiner noted,[12]

> Allochiria may be manifested when the power of localisation has only suffered to a slight degree, so that, with the exception of the error as to the side, the place touched was quite correctly indicated. It would therefore be erroneous to look upon allochiria merely as a symptom of great sensory impairment. I am of opinion it must be regarded as a completely distinct symptom

---

by itself. In favour of this also may be adduced the fact that, in very many cases of central neurosis, allochiria is altogether absent, notwithstanding the presence of a marked degree of anaesthesia.

Although uncertain as to the underlying mechanisms, Obersteiner suggested that the allochiria in the cases of myelopathy might be related to degeneration of the posterior columns. From a physiological perspective, he felt that his observations showed "that there is an intimate connection, in a sensory relationship, between corresponding regions of the body."[12]

Six months later, David Ferrier[13] reported another case of allochiria in *Brain* (1883), confirming "Obersteiner's view that allochiria must be regarded as a symptom not necessarily associated with anaesthesia." The patient had been under Ferrier's care at King's College Hospital, London, England, in 1881-1882. While engaged in his work as a carpenter, the patient had suffered a severe cranial injury when a scaffold-pole fell on his head from "some considerable height."[13] The major sequelae included ataxia and left hemiparesis. In regard to the sensory findings, Ferrier reported,[13]

> Tactile sensibility is throughout normal as regards delicacy and quickness of response, but there is a most remarkable condition of allochiria, or localisation of impressions on the wrong side, as well as a similar reversal of reflex response to tactile stimuli. . . . A touch on the right big toe was at once referred to the same spot on the left, and *vice versâ;* a similar condition existing on every point of both legs up to the groin. Above this, impressions were exactly localized on their proper side. . . . But, as has been stated, the reversal was not confined to perception of impressions, but extended also to reflex reaction. Tickling the sole of the one foot caused retraction of the other, while the foot actually tickled remained perfectly still. So also tickling of the inside of the one thigh caused flexion of the other. Conjoint tickling of the sole of the one foot and the inside of the other thigh caused reflex reactions of the foot and thigh.
>
> The unhesitating precision with which the patient referred the impression to the corresponding point on the side not touched, led me at first to suspect deception; but the absolute uniformity of the phenomena under every precaution against the patient knowing what was being done to test the condition, together with the reversal also of the reflex reactions, compelled me to abandon this hypothesis.

In the 25 years following Obersteiner's original description, 76 cases were reported to which the term allochiria was applied.[14] The majority were related to the sense of touch, but allochiric responses were also noted in relationship to pain, "muscle sense,"

Table 1.—Medical Dictionary Definitions of *Allochiria* and *Allesthesia*

Dictionary	Term	Greek Root	Definition
Black's Medical Dictionary[1]	*Allesthesia*	. . .	Not listed
	Allocheiria	. . .	Disorder of sensation in which sensations are referred to the wrong part of the body
Butterworths Medical Dictionary[2]	*Allachaesthesia* Allaesthesia	allache = elsewhere + aesthesia = no definition given	Touch sensation referred to a place distant from the point at which stimulus has been applied, but on the same side of the body; cf *allocheiria*
	Optical allachaesthesia	. . .	Transfer of an image by illusion from its proper quadrant in the visual field to the quadrant in a diagonal line opposite
	Allochaesthesia	. . .	Allachaesthesia
	Allocheiria	allos = other + cheir = hand	Alloaesthesia
Dorland's Illustrated Medical Dictionary[3]	*Allesthesia*	allos = other + aisthesis = perception-ia	A condition in which a sensation, as of pain or touch, is experienced at a point remote from that at which the stimulus is applied or occurs, as in allochiria
	Visual allesthesia	. . .	A condition in which visual images are transposed from one half of the visual field to the other, either vertically or horizontally; called also optical allachesthesia
	Allochiria	allo + cheir = hand + -ia	A condition in which, if one extremity is stimulated, the sensation is referred to the opposite side (Obersteiner)
Gould Medical Dictionary[4]	*Allachesthesia,* allachaesthesia	allache = elsewhere + esthesia	A tactile sensation experienced remote from the point of stimulation but on the same side of the body
	Allaesthesia	. . .	Allachesthesia
	Allesthesia, allaesthesia	. . .	Allachesthesia
	Allochaesthesia	. . .	Allachesthesia
	Allocheiria	allo + cheir- + ia	A form of allachesthesia in which the tactile sensation is experienced on the side opposite; the one to which the stimulus was applied, seen in tabes dorsalis and other conditions
	Allochesthesia, allochaesthesia		Allachesthesia
International Dictionary of Medicine and Biology[5]	*Allocheiria*	allo- + cheir- + -ia	Alloesthesia
	Allochesthesia	. . .	Alloesthesia
	Allochiria	allo(s) = other + cheir = hand + -ia	Alloesthesia
	Alloesthesia	allo- + -esthesia	A disorder of the localization of tactile stimuli, in which the patient feels the sensation at a corresponding point on the opposite side of the body to that to which the stimulus is applied. Also called allocheiria, allochiria, allochesthesia, Bamberger sign

(Continued on p 548.)

Table 1.—Medical Dictionary Definitions of *Allochiria* and *Allesthesia* (cont)

Stedman's Medical Dictionary[6]	*Allesthesia*	allos = other + aisthesis = sensation	Allocheira: alloesthesia; Bamberger's sign (2); a form of allachesthesia in which the sensation of a stimulus in one limb is referred to the opposite limb
	Visual allesthesia	. . .	A disorder characterized by the transposition of images from one half-field to the opposite
	Allocheiria, allochiria	allo- + cheir = hand	Allesthesia
	Allochiria	. . .	Alternative spelling for allocheiria (allesthesia)
Taber's Cyclopedic Medical Dictionary[7]	*Allesthesia*	allos = other + aisthesia = sensation	Perception of stimulus in the opposite limb from the one stimulated. Syn: allochesthesia; allochiria
	Allochesthesia	allache = elsewhere + aisthesia = sensation	Allesthesia
	Allochiria, allocheiria	allos = other + cheir = hand	Allesthesia

Table 2.—*Allochiria* and *Allesthesia* in Selected Neurology Textbooks

Clinical Neurology[8]	Optic allesthesia (false orientation of objects in space)
	Visual allesthesia is the transposition of an image to the opposite half of the field of vision
	A tactile stimulus applied to one part of the body may be projected to a corresponding spot on the opposite side (tactile allochiria)
	Pain induced by normally innocuous stimuli due to hyperesthesia of the region is known as allochiria
	The sudden appearance of pain in the homologous area of the body following cordotomy was due to reference pain also called allochiria
Medical Neurology[9]	Allochiria is a confusion of sides (ie, left from right) . . . This is a form of agnosia seen in lesions in or near the dominant angular gyrus as part of the Gerstmann syndrome
Principles of Neurology[10]	In alloesthesia or allesthesia, a tactile or painful stimulus delivered on the side of hemisensory loss is experienced in a corresponding area of the opposite side; this abnormality is observed most frequently with right-sided putaminal lesions (usually hemorrhage) and with anterolateral lesions of the cervical spinal cord
	Patients with an attention hemianopia may displace an image to the nonaffected half of the field of vision (visual allesthesia)
	False orientation of objects in space (optic allesthesia)
The Neurologic Examination[11]	The terms allachesthesia, allesthesia, and synesthesia are used when the sensation of touch is experienced at a site remote from the point of stimulation; allochiria means the referring of a sensation to the opposite side of the body

temperature, vision, smell, taste, hearing, and even reflex electrical movements. Allochiria was described as occurring in a number of diverse pathologic conditions, but most frequently in conjunction with tabes dorsalis or hysteria.[14] In their textbook, *Diseases of the Nervous System* (1899), Gowers and Taylor[14] defined allochiria as "a condition in which an impression on one part has been referred to the corresponding place on the opposite side of the body. Similar definitions were also employed by Ferrier, Church, Féré, Gay, Bury, Osler, F. Taylor, Head, Spearman, Hammond, Stewart, Marie, Dejerine, Brown-Séquard, Longuet, Gellé, Lapidous, Henri, Nothnagel, Strumpell, Von Leyden, Huber, Weiss, Hoffman, and Morselli.[14]

T. Grainger Stewart, who was later to collaborate with Gordon Holmes on important studies of cerebellar pathology, introduced the term *allachaesthesia* (ie, *allesthesia*) in an article published in the *British Medical Journal* in 1894.[15] Stewart described a 49-year-old man with a variety of somatic complaints and physical findings. The most striking neurological findings included a "perverted localization of sensation" in the left hemibody, rhythmical jerking of the right leg, chorea-like movements of the left leg and right hand, and an odd three-step corkscrew gait.[15] The major point of Stewart's article related to the sensory findings. In both the left arm and leg, he observed consistent horizontal displacements of localization for touch from the medial to the lateral portions, and vice versa. On the left trunk, horizontal and diagonal displacements were present. Stewart felt "that this and all our patient's symptoms are functional."[15] He noted the resemblance of these displacements to allochiria, but stated that they were obviously not the same since the displacements were on the same side of the body. In concluding, he designated a new name for this type of displacement[15]:

> The name allochiria has proved so useful in relation to the symptom which Obersteiner described, that I have thought it well to try to coin an expression which may serve as a name for this kind of faulty localisation, and, after consulting with my colleague, Professor Butcher, have decided to suggest the name, "allachaesthesia," from α'λλαχῆ, or α'λλαχοῦ, elsewhere, and α'ισθησία, perception, as the most satisfactory term that occurs to us.

Despite this precedence, Ernest Jones decided to redefine allochiria and allesthesia in an attempt to enhance the diagnostic specificity of allochiria.[14] Jones was a colleague and friend of Sigmund Freud. Jones aided Freud in his escape from Austria when the Nazis took power and was one of Freud's few colleagues who stayed with him to the end. After Freud's death, Jones authored a massive three-volume biography of his friend. Needless to say, Jones had an interest in hysteria. In 1907, he published one article in *Brain*[14] and one article in *Lancet*[16] reviewing the literature and detailing his view that allochiria "is always of psychical origin and that its presence is almost certain evidence of hysteria."[16]

To support his contention, Jones quoted Obersteiner out of context stating that allochiria is a condition in which "sensibility is retained more or less completely."[14] In fact, Obersteiner had pointed out that allochiria could occur with other sensory impairments, but could not be explained solely by simple sensory loss. Jones separated "true" allochiria from "false" allochiria (ie, allesthesia), and stated,[14]

> Obersteiner, who like all subsequent writers, did not recognise the distinction between the two classes, gave instances of both conditions in the cases he described in his original article. The one condition, false allochiria, is nothing more or less than alloaesthesia.... the mistake in alloaesthesia is essentially due to incomplete perception of the stimulus and is accompanied by many other failures in perception, such as defective localisation.

By redefining the terminology, Jones felt justified in claiming that allochiria had a "precise diagnostic value" and that the occurrence of allochiria "should be regarded as a positive indication of the presence of hysteria."[14] But, was he justified either historically or scientifically? Historically, his definitions do not fit the word derivations, the intent of the original authors, or even the general usage by the scientific community of that era. Scientifically, we know that allochiria, even under the restricted terms given by Jones, is not limited to hysteria. For example, cases that Jones would have attributed to a simple general sensory defect in localization (allesthesia by his definition) cannot be explained in this manner since the stimulus displacements are to the exact corresponding points on the opposite body. Further, a simple sensory defect cannot explain palinoptic visual allesthesia (ie, a persistent visual image in a spatial location remote from original stimulus).

Jones asserted that "it would be very curious if a peculiar phenomenon like allochiria could be produced in two quite different ways."[14] In fact, it would be more curious if such a complex behavioral symptom that spans such a variety of underlying disease processes (eg, myelopathies, neglect syndrome, diffuse organic brain syndromes, hysteria, and parieto-occipital tumors with palinoptic visual allochiria) could be explained by a single mechanism. Jones confused symptom with function, a mistake commonly made in the 19th century regarding localization of function, and a mistake that continues in this century despite the writings of Hughlings Jackson and others. Like most neurologic signs and symptoms, allochiria takes on its anatomic and pathophysiologic significance from the full pattern of neurologic findings. For example, the allochiria seen in myelopathies may depend on an uncrossed ipsilateral spinothalamic pathway,[10] but allochiria following right-sided cerebral lesions may depend on alterations in attentional/intentional mechanisms.[17]

The views expressed by Jones in his articles of 1907 were not seriously challenged, and, excluding studies on local sensory displacements (eg, Henry Head), writings on allochiria and allesthesia all but disappeared until the middle of the 20th century, when Morris Bender[18] began his extensive studies on the phenomenon of sensory displacement. In 1948, Bender described a case of transbody tactile mislocations in a patient exhibiting "slight impairment of two point discrimination and point localization." He employed the term *allesthesia*, accepting Jones' definition that "allochiria" can occur only in the complete absence of sensory deficits.[19] However, simple sensory deficits cannot explain the transbody mislocations, a point that is all the more clear in later cases described by Bender and colleagues.[20] For example, a graphic depiction of mislocations in a patient with left-sided hypalgesia from a 1949 article by Bender et al[20] demonstrates dramatically that the mislocations do not occur in a random pattern, which would be expected if produced by a simple defect in localization. The use of *allesthesia* in these cases is not strictly incorrect since allochiria is a subset of allesthesia. However, the use of *allochiria* is more precise since it implies a different phenomenon that cannot be explained by a simple sensory deficit.

In conclusion, Jones' reinterpretation of allochiria and allesthesia is not justified historically, etymologically, or scientifically, and has resulted in contradictory definitions in present-day medical dictionaries and neurological textbooks.[1-11] We advocate a return to usage more consistent with the original descriptions and word derivations. Thus, *allesthesia* is a condition in which a sensory impression is mislocated to a remote position, and *allochiria* denotes mislocations to the corresponding opposite half of the body or space.

Dr Meador is a recipient of the National Institute on Aging-National Institutes of Health Clinical Investigator award K08-AG00314.

The authors thank A. Papanicolaou, PhD, for his comments and R. Marx and P. Turner for typing the manuscript.

Professional Opportunities

NEUROLOGIST: Excellent opportunity for board-certified/board-eligible neurologists to join two existing neurologists in a stimulating, busy practice. Marquette General Hospital is a 321-bed regional referral center, with a comprehensive neurophysiology department and state-of-the-art technology that includes magnetic resonance imaging and CT scanning, and a hospital-based family practice residency. Medical students from Michigan State University's College of Human Medicine are regularly assigned to the hospital and offer an opportunity for teaching. Marquette General Hospital and its medical staff are committed to building a center of excellence in the neurosciences and have the necessary financial resources. The development of these services will require the leadership and cooperation of physicians in the field of neurology, neurosurgery, psychiatry, physical medicine and rehabilitation. Salaried and private practice positions are available. If this special opportunity is of interest to you, please send CV to: Robert J. Raica, Marquette General Hospital, 420 West Magnetic Street, Marquette, MI 49855.

BC/BE NEUROLOGIST NEEDED — California. Excellent opportunity to establish your own private practice with no investment, guaranteed income. Strong referral base. Proficiency in EEG/EMG required. Well equipped, 112-bed, full-service hospital. Our service area population is now 90,000; a growing area with new businesses and stable economy. Located in central California near Sequoia National Park, Tulare offers an excellent family-oriented lifestyle and all expected amenities. Beautiful homes close to hospital and office are affordably priced. Good schools, many community activities and abundant recreation including golf, tennis, mountain and equestrian activities. Easy access to all California's major metropolitan and resort areas. Please contact: Tulare District Hospital Physician Recruiting Office, P.O. Box 90112, Los Angeles, CA 90009. (800) 468-2687.

NEUROLOGIST to join dynamic, midwest neurology group. This very busy practice is seeking an energetic neurologist with a strong interest in the clinical care of patients. This opportunity is located in a desirable, midwestern community abundant in cultural and sporting activities. The practice has a well-equipped radiology department with MRI and CT, and also, neurophysiology and neuropsychology departments. The appropriate candidate must be energetic, pleasant, BC/BE, with EMG experience. Please send curriculum vitae to: Box #814, c/o AON.

CHARLOTTE, NORTH CAROLINA: High quality group of six neurologists, all of whom are subspecialized, seeks to add a well-trained specialist. Contact: Mike Kaufman, MD, 126 Cottage Place, Charlotte, NC 28207. Or call: (704) 334-7311.

FLORIDA'S CENTRAL EAST COAST—Adult neurologist with EMG training wanted to join group of eight neurologists. We live an a high tech, beachside community with great schools and affordable housing. Please send CV to: Search Committee, P.O. Box 693, Melbourne, FL 32902.

JULY 1991 — ASSOCIATE WANTED. Outstanding opportunity. $200K net probable by end of first year. Fully equipped neurologic institute. Only the best need apply. Send CV at once: Southeastern Neuroscience Institute, Inc., 5143 University Boulevard, West, Suite 3, Jacksonville, FL 32216-5939. (904) 733-0707; FAX (904) 730-9173.

PLEASE NOTE—Address replies to box number ads as follows: Box number, _____, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

Professional Opportunities

EXCELLENT OPPORTUNITY for BC/BE neurologist to join 80-physician, comprehensive, multispecialty group in San Francisco Bay Area. Large, varied referral base from pediatrics, IM, FP, and surgery. EMG/NCV, EEG, evoked response testing, CT, MRI, radiology support all available on site. Opportunity to interface with sepcialists of all types including neurosurgeons. Major university teaching affiliation encouraged and possible. Close proximity to 400-bed full service, modern hospital serving population of 300,000. Competitive guaranteed salary with bonus productivity plan for initial 18 months leading to partnership track. Extensive benefit package including housing incentives. Unique cultural, recreational and educational opportunities. Send CV to: Gary D. Zweig, MD, Recruitment Chairman, Sunnyvale Medical Clinic, P.O. Box 3496, Sunnyvale, CA 94088-3496.

NEUROLOGIST

Neurologist, board-eligible or board-certified, with EEG, EMG, EP and neuro-CT needed to join an adult neurologist in a 32-physician multi-specialty clinic, 100 miles southeast of St. Louis. Population 28,000 plus 25,000 Southern Illinois University students.

Opportunity exists for affiliation with SIU Medical School. No capital investment. Flexible compensation package with generous fringe benefits including health and disability, vacation, CME leave, and profit sharing retirement plan.

Carbondale, IL 62901 ◆ (618) 549-5361

THIRD NEUROLOGIST, BC/BE, desired for growing neurology practice in southern Michigan. EMG/EEG expertise and strong clinical skills required. Wide referral base. Equipped neurophysiological laboratory available. Exceptional lifestyle and cultural resources. Attractive salary and incentives leading to parternship in one year. Please write to: Neill S. Hirst, MD, 250 West Eisenhower Parkway, Suite 100, Ann Arbor, MI 48103. Or call: (313) 665-6638.

ATTENTION PHYSICIAN RECRUITERS. The "Classified Advertising" sections now in all nine AMA Specialty Journals target the physician you want. These highly visible sections put your message in the hands of every specialist that qualifies for your professional opportunity, every month. To place the ad of your choice, any size, call toll free: (800) 237-9851.

CHICAGO — BC/BE neurologist to join existing practice. Highly motivated individual with strong clinical skills and EMG/EEG expertise needed to join two busy neurologists. Very strong medical school affiliation with teaching responsibilities for neurology and internal medicine, residents and medical students. Large referral base. Excellent benefit package. Please provide CV. Please contact: Box #818, c/o AON.

Professional Opportunities

EXPANDING, DYNAMIC ADULT neurology practice — BC/BE neurologist to join rapidly growing office and multi-hospital practice in New Jersey — 15 minutes from Manhattan. Candidate must be energetic and personable. EMG, EEG experience preferred. Send CV to: Joseph Sobelman, MD, 834 Avenue C, Bayonne, NJ 07002.

MAUI ORTHOPEDIC and Sports Medicine seeks neurologist to establish independent practice. Contact: William Gfeller, 450 Hookāhi Street, Wailuku, Maui, HI 96793. (808) 244-5541.

SOUTHEAST COAST — The Neuroscience Center of a 190-bed regional medical center is seeking a BC/BE neurologist to join in close association with their existing neurosurgeons. Exceptional medical facilities and neurological services including EEG/EMG, EP, CT, MRI. Excellent income guarantee plus benefits — large drawing area provides for outstanding potential. Located ninety minutes from one of this country's premiere seaside resorts, this dynamic community offers a quality lifestyle. Call Mark Prosperi at (800) 776-5776 for more details or send CV to: Cejka & Co., 1034 South Brentwood Boulevard, St. Louis, MO 63117.

DENVER — Extremely busy, five-physician group with three Denver area offices are now seeking their fourth neurologist. Two members are neurosurgeons. Send CV to: Gordon Crawford, Manager, Professional Relations, Humana Inc., Department AN-5A, 500 West Main Street, Louisville, KY 40201-1438. Or call toll-free (800) 626-1590.

SOUTHEAST COAST — Pediatric Neurologist: Excellent quality of life available in Savannah-Hilton Head Area, site of the 1996 Olympic Games sailing events. Outstanding recreational opportunities, nation's largest urban Historic District, and superb symphony are among the attractions of living here. A well-trained, personable neurologist with special competence in child neurology is needed for a busy practice, currently consisting of two adult neurologists and one neurologist doing adult and child neurology, all with strong academic backgrounds. CT, EEG, EMG and physical therapy are available in-office with large hospital practice available in three hospitals, including a major regional teaching hospital, affiliated with the Medical College of Georgia. First year guarantee is $80,000 plus bonus, leading to full partnership after two years. Earnings potential, availability of strong multi-specialty support, and opportunities for teaching are extraordinary. If interested contact: Randy Wellman, Office Manager, Savannah Neurological Associates, PC, P.O. Box 23059, Savannah, GA 31403. (912) 354-8151.

ADULT NEUROLOGIST to associate with two separate, busy solo neurologists. Practices are referral based, with two separate offices and three voluntary hospitals. Successful candidate would be expected to develop a separate solo, but collaborative practice. Established physicians would expect to provide substantial support for beginning physician. Opportunity would provide for cross coverage and joint venturing of facilities. Successful candidate should have excellent clinical skills. The medical community has excellent neurophysiology, neuroradiology, and neurosurgery. Located in a medium size city with both excellent living conditions and an extremely solid economic base. Please contact: Jeffrey A. Ribner, MD, 503 Plaza Drive, Vestal, NY 13850. (607) 729-1521 or Robert R. Taylor, Jr., MD, 269 Riverside Drive, Johnson City, NY 13790. (607) 798-7143.

SEEKING ENERGETIC BE/BC NEUROLOGIST to join three adults and one child neurologist. Prefer someone with interest in general neurology and special interest and training in any of the following areas: sleep medicine, neurophysiology testing, neuro-rehabilitation, pain, or neuro-intensive care. Excellent medical community with all of the supportive consultants and technology. Send CV to: Neurological Associates of Grand Rapids, PC, 2855 Michigan Street, Northeast, Grand Rapids, MI 49506.

IMMEDIATE OPENING, for neurologists, full-time or part-time, to join practice in the Washington/Baltimore Corridor area of Maryland. Reply with CV to: Maryland Neurological Center, 11085 Little Patuxent Parkway, Suite #212, Columbia, MD 21044. Attention: Personnel Department.

Professional Opportunities

NEUROLOGIST — Greene Clinic, a prestigious, well-established clinic, wishes to add a neurologist to its staff. The offices are in a new, $5.5 million, state-of-the-art facility, located in a university town outside a major metropolitan area. The directorship of the head injury unit at the local rehab hospital is also available along with the position, but not a requirement. A superior salary/compensation package is offered. If interested, please call: Kevin McGrane at (800) 776-5776 to explore this excellent opportunity further.

ARE THERE professional settings you've always wanted to sample? Consider joining CompHealth, the nation's largest locum tenens group. If you qualify, you can practice from Florida to Alaska — for a week to several years or anything in between — it's your choice. You'll enjoy the experience of a lifetime. CompHealth provides competitive earnings and takes care of the malpractice premiums and major expenses like housing and transportation. What's more, you'll spend less time on paperwork and more time on quality health care. Openings available now. Call: (800) 328-3043 toll-free.

EXCELLENT OPPORTUNITY for BC/BE neurologist to practice in large eastern metropolitan area. Immediate opening for private practice with geographic full-time appointment at large teaching institution. Medical school appointment, teaching and research opportunities. Subspecialty in movement disorders, muscle diseases or neuro-oncology preferred but not required. Submit CV to: P.O. Box 5849, Pittsburgh, PA 15209-0849.

NEUROLOGIST — BC/BE, full- or part-time, for exanding San Francisco Bay area. Private practice with emphasis on clinical occupational neurology and med-legal evaluations. Expertise in EMG, EEG and EP desired. Excellent reputation, referral base, facilities and support staff. Unique income opportunity. Submit CV and letter stating professional goals, and availability to: Personnel, 2040 Polk Street, Box 337, San Francisco, CA 94109.

NEUROLOGIST

Minneapolis/St. Paul — BC/BE adult neurologist wanted to join four other neurologists in a diverse practice consisting of both inpatient and outpatient settings. Group Health, Inc. is a non-profit, member governed HMO with one of the largest multi-specialty group practices in the Midwest. Our physicians are given the ability to focus on practicing high quality, cost-effective medicine in an environment that is relatively free of administrative duties. The Twin Cities are recognized as one of the best areas in the country to raise a family. The communities provide excellent schools, countless cultural events, numerous recreational activities, and a myriad of lakes and parks.

Observation

Germ Cell Tumors Masquerading as Central Nervous System Sarcoidosis

David M. Peeples, MD; Barney J. Stern, MD; Violet Jiji, MD; K. Singh Sahni, MD

• The diagnosis of central nervous system sarcoidosis is uncertain without typical multisystem involvement. We describe two patients with isolated central nervous system mass lesions whose biopsy results were consistent with sarcoidosis. After a progressive clinical course, they were found to have diencephalic germinomas. Germ cell tumors, in particular, should be considered in the differential diagnosis of central nervous system sarcoidosis as they are potentially treatable, occur in intracranial locations favored by sarcoidosis mass lesions, and may be surrounded by granulomatous inflammation that can be mistaken for the noncaseating granulomas of sarcoidosis.

(*Arch Neurol.* 1991;48:554-556)

Intracranial granulomatous mass lesions can arise from diverse pathogenic mechanisms. Infectious processes, inflammatory disorders, and neoplastic disease can all result in granulomatous reactions. Sarcoidosis can present with isolated central nervous system (CNS) involvement,[1] occasionally in the form of a mass lesion[2]; systemic manifestations are typically found or develop over time. We describe two patients with diencephalic granulomatous mass lesions that were initially thought to represent CNS sarcoidosis, but were found, after relentless progression, to be germ cell tumors.

REPORT OF CASES

CASE 1.—A 37-year-old white man presented in October 1985 with polyuria and polydipsia. Evaluation revealed a partial antidiuretic hormone deficiency, positive purified protein derivative tuberculin, and a 2.5-cm suprasellar contrast-enhancing mass on computed tomographic scan. A chest roentgenogram revealed old granulomas. Results of lacrimal gland biopsy and angiotensin-converting enzyme levels were normal, as were serum and cerebrospinal fluid β–human chorionic gonadotrophin and α-fetoprotein levels. A stereotactic biopsy specimen showed a mononuclear cell infiltrate consistent with granulomatous disease. The patient was treated with desmopressin acetate (dDAVP), isoniazid, and rifampin. In October 1986, diminished visual acuity occurred, and computed tomographic scans revealed a slight increase in the size of the lesion (Fig 1, left). The diagnosis of sarcoidosis was made, and prednisone therapy (80 mg/d) was initiated. In December 1986, the patient developed headaches, a postchiasmatic syndrome with a right homonymous hemianopsia and a left inferior quadrantanopsia, and tinnitus and hearing loss in the right ear. His cerebrospinal fluid was acellular (protein, 0.96 g/L; and glucose, 3.2 mmol/L). He underwent surgical exploration in January 1987; the mass had a friable appearance and was adherent to the hypothalamus. Pathologic examination revealed inflammatory cells with a granulomatous reaction consistent with sarcoidosis. Acid-fast bacilli and fungal stains and cultures were negative. Prednisone therapy (140 mg/d) improved the patient's visual and aural symptoms, but by April 1987 he again developed progressive visual loss and constricted visual fields. Complete reevaluation for systemic sarcoidosis was negative, and in May 1987 cyclosporine was administered in addition to prednisone as part of an investigational study for refractory neurosarcoidosis. In July 1987 the findings of the patient's neurologic examination were unchanged, but a computed tomographic scan of his cranium revealed further enlargement of the mass (Fig 1, right). He developed *Pneumocystis carinii* pneumonia and died after a respiratory arrest.

Autopsy revealed a 5.5 × 2.0 × 1.1-cm pedunculated mass composed of gray, somewhat rubbery tissue protruding from the sella turcica, involving both optic nerves, the optic chiasm, and the pituitary stalk, and loosely adherent to the base of the third ventricle and hypothalamus. Microscopic examination revealed a germinoma composed of sheets of large round cells with pale cytoplasm and hyperchromatic nuclei. Lymphoid cells were infiltrating between the tumor cells and fibrovascular stroma. No granulomas were seen (Fig 2). The eighth cranial nerves were normal.

CASE 2.—A 16-year-old white boy presented in January 1987 with headaches, papilledema, and a small enhancing lesion obstructing the foramen of Monroe (Fig 3, left). Ventriculoperitoneal shunting was followed by a right frontal craniotomy and a biopsy, which revealed a granulomatous reaction in the floor of the third and left lateral ventricles, consistent with sarcoidosis (Fig 4, left). There was no tumor found, and acid-fast bacilli, fungal, and mucin stains were negative. Analysis of cerebrospinal fluid showed 8

Accepted for publication November 7, 1990.

From the Department of Neurology, The Johns Hopkins Medical Institutions, Baltimore, Md (Drs Peeples and Stern); the Division of Neurology (Dr Stern) and the Department of Pathology (Dr Jiji), Sinai Hospital of Baltimore (Md); and the Department of Neurosurgery, Medical College of Virginia, Richmond (Dr K. Singh Sahni).

Reprint requests to Division of Neurology, Sinai Hospital of Baltimore, Baltimore, MD 21215 (Dr Stern).

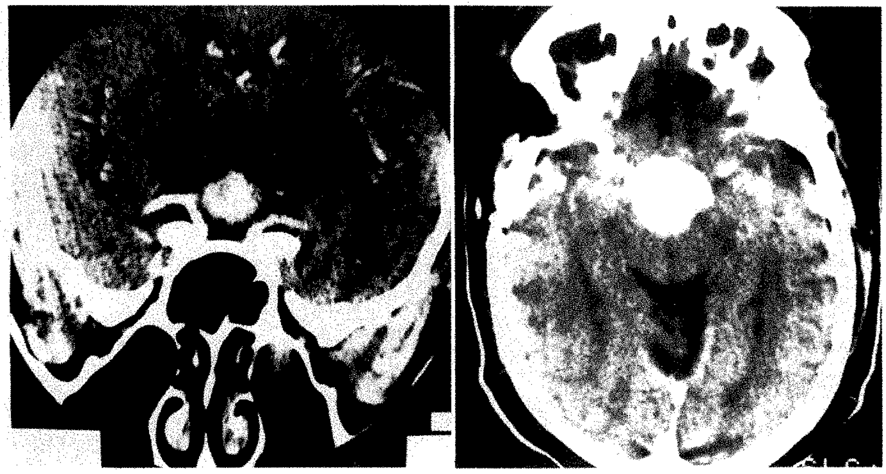

Fig 1.—Left, Contrast-enhanced computed tomographic scan of patient 1 reveals a discrete suprasellar mass. Right, Contrast-enhanced computed tomographic scan of the same patient 9 months later shows enlargement of the mass.

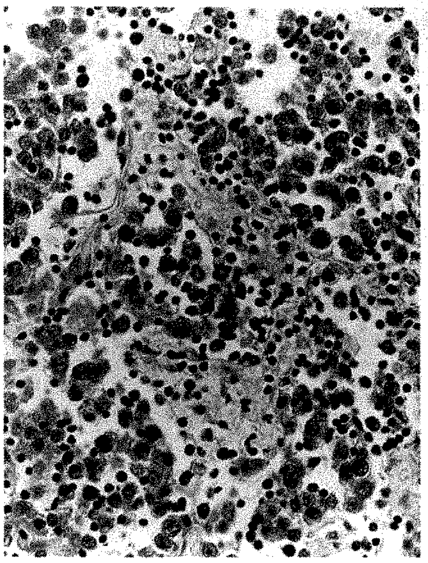

Fig 2.—Representative histologic section of the germinoma obtained at autopsy of patient 1 reveals characteristic germinoma cells in a loose vascular stroma with interspersed lymphocytes (hematoxylin-eosin, ×320).

monocytes; protein, 0.34 g/L; and glucose, 4.3 mmol/L; the cytopathologic findings were negative. Systemic evaluation for sarcoidosis was unrevealing. Prednisone therapy (40 mg/d) was initiated. In July 1987 a computed tomographic scan revealed extensive enhancement in the anterior third ventricle and hypothalamus. The patient developed mild central hypopituitarism, with slightly low thyrotropin, thyroxine, and testosterone levels. Weekly infusions of methylprednisolone (30 mg/kg) were begun, but by September 1987 there was a 3-cm intraventricular enhancing mass (Fig 3, right), and a hypothalamic syndrome with hyperpyrexia, hypersomnolence, and diabetes insipidus had developed. In October 1987 a large heterogeneous third ventricular mass was removed. Pathologic examination revealed malignant germinoma, composed predominantly of embryonal carcinoma and focal teratoma (Fig 4, right). There was extensive necrosis and granulomatous inflammation. An immunoperoxidase α-fetoprotein stain was positive. Postoperatively, the patient did poorly, with rapid tumor recurrence despite radiation therapy and chemotherapy. He died of sepsis several months later.

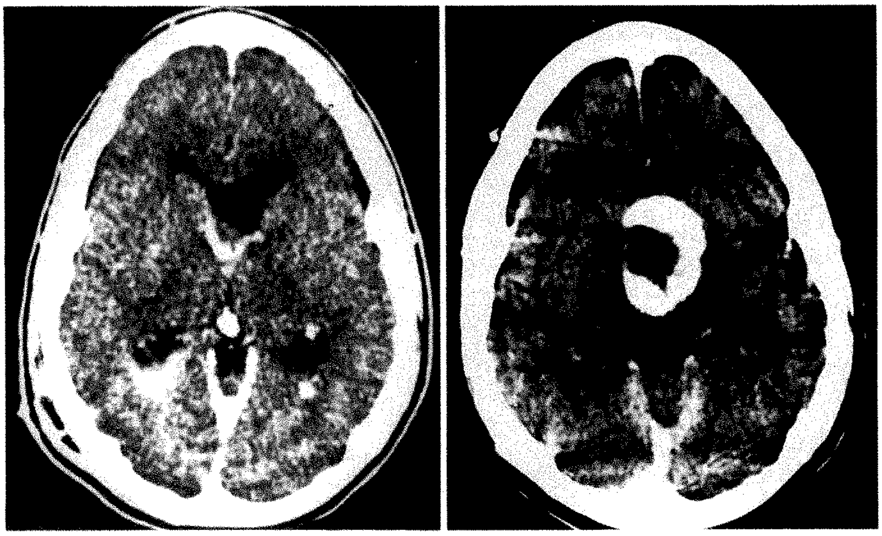

Fig 3.—Left, Contrast-enhanced computed tomographic scan of patient 2 reveals an enhancing lesion near the third ventricle and dilatation of the left lateral ventricle. Right, Contrast-enhanced computed tomographic scan of the same patient 8 months later reveals a large cystic mass.

COMMENT

Sarcoidosis is a multisystem granulomatous disease of unknown origin with neurologic manifestations in 5% of cases.[1,3,4] Nearly 50% of patients with neurosarcoidosis will have neurologic symptoms as the initial feature of their illness. Although rare, isolated granulomatous mass lesions can be the sole clinical manifestation of sarcoidosis.[2] The suprasellar region is a characteristic site, and diabetes insipidus, as in our first patient, is not an unusual presentation.[5] Nevertheless, multisystem involvement is the rule: one autopsy study found disseminated disease to be common despite isolated neurologic symptoms,[6] and another clinical series of 50 consecutive patients with neurosarcoidosis reported that of 24 who presented with neurologic symptoms, systemic involvement eventually developed in all but five.[1]

Both our patients were white males who lacked the stigmata of multisystem sarcoidosis such as elevated serum angiotensin-converting enzyme levels, adenopathy, uveitis, or pulmonary inflammation. Neurosarcoidosis was entertained on the basis of biopsy of the CNS lesion, twice in our first patient, which revealed no evidence of neoplasia or infection. Although a granulomatous CNS mass lesion could be either true isolated CNS sarcoidosis or simply a harbinger of systemic involvement, the lack of evidence for multisystem sarcoidosis makes a diagnosis, even on the basis of biopsy, far less certain. Furthermore, concurrent corticosteroid treatment can make detection of inflammation in other organs difficult.

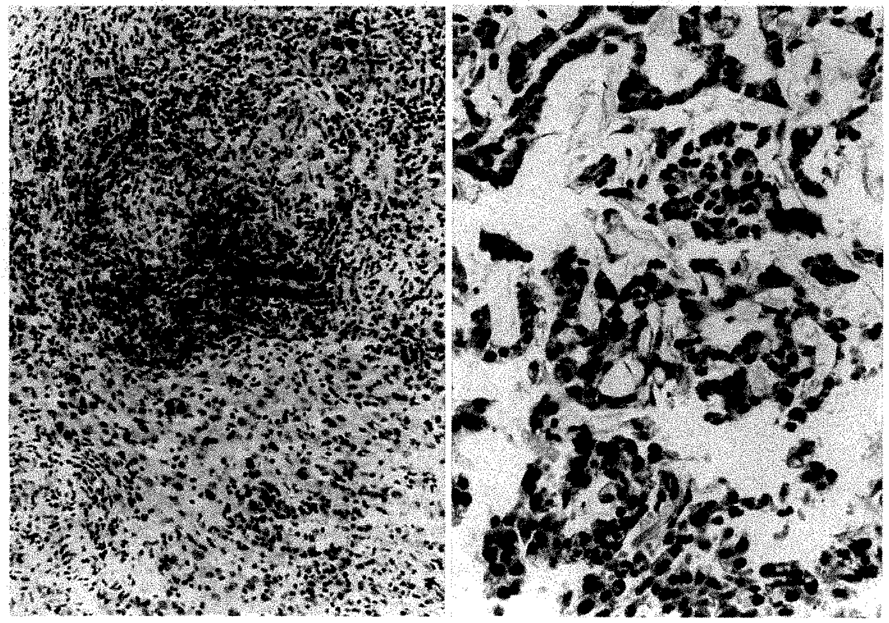

Fig 4.—Left, Section of open biopsy specimen from patient 2 reveals granulomatous inflammation (hematoxylin-eosin, ×320). Right, Second biopsy specimen obtained 8 months later shows a malignant germ cell tumor with features of an embryonal carcinoma (hematoxylin-eosin, ×320).

Although noncaseating granulomas are the pathologic hallmark of sarcoidosis, granulomatous inflammation is nonspecific and must be considered within the clinical framework. Granuloma formation can arise from diverse processes including tuberculosis, atypical mycobacteria, fungal infections, syphilis, brucellosis, actinomycosis, tularemia, leprosy, vasculitis, and foreign body reactions and as a response to certain neoplasms. Histologically, the sarcoidosis granuloma is composed of large pale-pink epithelial cells with interspersed giant cells and lymphocytes. Caseation is not prominent, but may occur and cause confusion with tuberculosis. Schaumann's and asteroid bodies are perhaps most common in sarcoidosis granulomas, but they are not pathognomonic features and cannot be reliably used as diagnostic criteria.[7]

The treatment of CNS sarcoidosis mass lesions typically begins with corticosteroid therapy. In refractory cases, or when decompensation is imminent owing to mass effect, high-dose corticosteroid therapy, treatment with other immunosuppressive agents, surgical exploration, and radiotherapy are often considered.[4] These interventions can occasionally lead to further diagnostic confusion. For instance, lymphoma may respond to corticosteroid or radiation therapy. The possibility of alternative diagnoses should always be kept in mind and aggressively excluded.

Intracranial germ cell tumors, also called atypical teratoma or ectopic pinealoma, are rare.[8] They usually occur in the pineal region, causing increased intracranial pressure and Parinaud's ophthalmoplegia. A suprasellar location is the second most common site. Diabetes insipidus can be an early sign, with the late development of hypopituitarism, hypothalamic dysfunction, visual field defects, and raised intracranial pressure. Symptoms and sites of involvement are strikingly similar to sarcoidosis mass lesions. Furthermore, a granulomatous reaction is common in the periphery of such lesions, and the malignancy can be missed on biopsy if the core of the tumor is not obtained.[9] Some germinomas secrete α-fetoprotein, β–human chorionic gonadotrophin, or placental alkaline phosphatase.[10] An elevated cerebrospinal fluid angiotensin-converting enzyme level has been documented in a patient with a suprasellar germinoma,[11] a finding that can occur in CNS sarcoidosis and thereby further contribute to diagnostic confusion.[12] One of our patients had no tumor markers at presentation, and the other was not evaluated prior to tumor debulking, at which time the tissue had a positive α-fetoprotein immunoperoxidase stain. It is possible that if elevated cerebrospinal fluid levels of α-fetoprotein had been detected, an earlier diagnosis might have been possible. There is an excellent response of germ cell tumors to radiotherapy,[8,13,14] highlighting the importance of accurate diagnosis.

Without the stigmata of multisystem disease, basing the diagnosis of CNS sarcoidosis on the biopsy specimen of a mass lesion demonstrating noncaseating granulomas is fraught with uncertainty. Our two cases illustrate several important aspects in the management of patients with granulomatous mass lesions from presumed isolated CNS sarcoidosis: (1) The diagnosis of CNS sarcoidosis is most certain if multisystem disease is demonstrated. (2) Biopsy of a mass lesion can miss the primary pathologic process and reveal only a nonspecific granulomatous reaction. (3) If clinical progression occurs, with enlargement of the mass lesion despite aggressive corticosteroid therapy, continued search for systemic disease and another biopsy, if possible, are indicated to rule out infection or neoplasia. (4) Corticosteroid therapy may mask the stigmata of disease at other sites. (5) Germ cell tumors, in particular, need to be considered because they are potentially treatable, frequently occur at intracranial locations favored by sarcoidosis, and have a prominent surrounding granulomatous reaction.

Richard J. Otenasek, Jr, MD, referred patient 2. We thank Ed Koo, MD, who reviewed the pathology specimens, and Gwendolyn Boyd and Charlie Harper, who helped prepare the manuscript.

Dilantin® KAPSEALS® (Extended Phenytoin Sodium Capsules, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows.

INDICATIONS AND USAGE: Dilantin is indicated for the control of generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and prevention and treatment of seizures occurring during or following neurosurgery.

Phenytoin serum level determinations may be necessary for optimal dosage adjustments (see Dosage and Administration and Clinical Pharmacology in the full prescribing information).

CONTRAINDICATIONS: Phenytoin is contraindicated in those patients who are hypersensitive to phenytoin or other hydantoins.

WARNINGS: Abrupt withdrawal of phenytoin in epileptic patients may precipitate status epilepticus. When, in the judgment of the clinician, the need for dosage reduction, discontinuation, or substitution of alternative antiepileptic medication arises, this should be done gradually. However, in the event of an allergic or hypersensitivity reaction, rapid substitution of alternative therapy may be necessary. In this case, alternative therapy should be an antiepileptic drug not belonging to the hydantoin chemical class.

There have been a number of reports suggesting a relationship between phenytoin and the development of lymphadenopathy (local or generalized) including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin's Disease. Although a cause and effect relationship has not been established, the occurrence of lymphadenopathy indicates the need to differentiate such a condition from other types of lymph node pathology. Lymph node involvement may occur with or without symptoms and signs resembling serum sickness, eg, fever, rash and liver involvement.

In all cases of lymphadenopathy, follow-up observation for an extended period is indicated and every effort should be made to achieve seizure control using alternative antiepileptic drugs.

Acute alcoholic intake may increase phenytoin serum levels while chronic alcoholic use may decrease serum levels.

In view of isolated reports associating phenytoin with exacerbation of porphyria, caution should be exercised in using this medication in patients suffering from this disease.

Usage in Pregnancy: A number of reports suggests an association between the use of antiepileptic drugs by women with epilepsy and a higher incidence of birth defects in children born to these women. Data are more extensive with respect to phenytoin and phenobarbital, but these are also the most commonly prescribed antiepileptic drugs; less systematic or anecdotal reports suggest a possible similar association with the use of all known antiepileptic drugs.

The reports suggesting a higher incidence of birth defects in children of drug-treated epileptic women cannot be regarded as adequate to prove a definite cause and effect relationship. There are intrinsic methodological problems in obtaining adequate data on drug teratogenicity in humans; genetic factors or the epileptic condition itself may be more important than drug therapy in leading to birth defects. The great majority of mothers on antiepileptic medication deliver normal infants. It is important to note that antiepileptic drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures, because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus. The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

In addition to the reports of increased incidence of congenital malformation, such as cleft ip/palate and heart malformations, in children of women receiving phenytoin and other antiepileptic drugs, there have more recently been reports of a fetal hydantoin syndrome. This consists of prenatal growth deficiency, microcephaly and mental deficiency in children born to mothers who have eceived phenytoin, barbiturates, alcohol, or trimethadione. However, these features are all nterrelated and are frequently associated with intrauterine growth retardation from other causes.

There have been isolated reports of malignancies, including neuroblastoma, in children whose mothers received phenytoin during pregnancy.

An increase in seizure frequency during pregnancy occurs in a high proportion of patients, because of altered phenytoin absorption or metabolism. Periodic measurement of serum phenytoin levels is particularly valuable in the management of a pregnant epileptic patient as a guide to an appropriate adjustment of dosage. However, postpartum restoration of the original dosage will probably be indicated.

Neonatal coagulation defects have been reported within the first 24 hours in babies born to pileptic mothers receiving phenobarbital and/or phenytoin. Vitamin K has been shown to prevent r correct this defect and has been recommended to be given to the mother before delivery and o the neonate after birth.

PRECAUTIONS: General: The liver is the chief site of biotransformation of phenytoin; patients with impaired liver function, elderly patients, or those who are gravely ill may show early signs f toxicity.

A small percentage of individuals who have been treated with phenytoin has been shown to metabolize the drug slowly. Slow metabolism may be due to limited enzyme availability and lack f induction; it appears to be genetically determined.

Phenytoin should be discontinued if a skin rash appears (see "Warnings" section regarding drug scontinuation). If the rash is exfoliative, purpuric, or bullous or if lupus erythematosus, Stevens-ohnson syndrome, or toxic epidermal necrolysis is suspected, use of this drug should not be sumed and alternative therapy should be considered. (See Adverse Reactions.) If the rash is a milder type (measles-like or scarlatiniform), therapy may be resumed after the rash has ompletely disappeared. If the rash recurs upon reinstitution of therapy, further phenytoin edication is contraindicated.

Phenytoin and other hydantoins are contraindicated in patients who have experienced henytoin hypersensitivity. Additionally, caution should be exercised if using structurally similar g, barbiturates, succinimides, oxazolidinediones and other related compounds) in these same atients.

Hyperglycemia, resulting from the drug's inhibitory effects on insulin release, has been ported. Phenytoin may also raise the serum glucose level in diabetic patients.

Osteomalacia has been associated with phenytoin therapy and is considered to be due to henytoin's interference with Vitamin D metabolism.

Phenytoin is not indicated for seizures due to hypoglycemic or other metabolic causes. ppropriate diagnostic procedures should be performed as indicated.

Phenytoin is not effective for absence (petit mal) seizures. If tonic-clonic (grand mal) and sence (petit mal) seizures are present, combined drug therapy is needed.

Serum levels of phenytoin sustained above the optimal range may produce confusional states referred to as "delirium," "psychosis," or "encephalopathy," or rarely irreversib dysfunction. Accordingly, at the first sign of acute toxicity, plasma levels are recomm reduction of phenytoin therapy is indicated if plasma levels are excessive; if symp termination is recommended. (See Warnings.)

Dilantin® Kapseals®

(extended phenytoin sodium capsules, USP)

Information for Patients: Patients taking phenytoin should be advised of the i adhering strictly to the prescribed dosage regimen, and of informing the physician condition in which it is not possible to take the drug orally as prescribed, eg, sur

Patients should also be cautioned on the use of other drugs or alcoholic beverage seeking the physician's advice.

Patients should be instructed to call their physician if skin rash develops.

The importance of good dental hygiene should be stressed in order to development of gingival hyperplasia and its complications.

Do not use capsules which are discolored.

Laboratory Tests: Phenytoin serum level determinations may be necessary to ac dosage adjustments.

Drug Interactions: There are many drugs which may increase or decrease pheny which phenytoin may affect. Serum level determinations for phenytoin are espe when possible drug interactions are suspected. The most commonly occurring dru are listed below: 1. Drugs which may increase phenytoin serum levels include: a intake, amiodarone, chloramphenicol, chlordiazepoxide, diazepam, dicumarol, estrogens, H_2-antagonists, halothane, isoniazid, methylphenidate, phen phenylbutazone, salicylates, succinimides, sulfonamides, tolbutamide, trazodon

2. Drugs which may decrease phenytoin levels include: carbamazepine, chronic al reserpine, and sucralfate. Moban® brand of molindone hydrochloride contains c which interfere with the absorption of phenytoin. Ingestion times of phenytoin preparations containing calcium should be staggered in patients with low serum phe to prevent absorption problems.

3. Drugs which may either increase or decrease phenytoin serum levels include: ph sodium valproate, and valproic acid. Similarly, the effect of phenytoin on phenobarb acid and sodium valproate serum levels is unpredictable.

4. Although not a true drug interaction, tricyclic antidepressants may precipitat susceptible patients and phenytoin dosage may need to be adjusted.

5. Drugs whose efficacy is impaired b include: corticosteroids, coumarin anti digitoxin, doxycycline, estrogens, furos contraceptives, quinidine, rifampin, th vitamin D.

Drug/Laboratory Test Interactions: Phe cause decreased serum levels of protein-b (PBI). It may also produce lower than norm dexamethasone or metyrapone tests. Phe cause increased serum levels of glucose, al phatase, and gamma glutamyl transpepti

Carcinogenesis: See "Warnings" section f tion on carcinogenesis.

Pregnancy: See Warnings.

Nursing Mothers: Infant breast-feeding is not recommended for women taking this dr phenytoin appears to be secreted in low concentrations in human milk.

ADVERSE REACTIONS: Central Nervous System: The most common manifestations with phenytoin therapy are referable to this system and are usually dose-related. Th nystagmus, ataxia, slurred speech, decreased coordination and mental confusion. insomnia, transient nervousness, motor twitchings, and headaches have also been obse have also been rare reports of phenytoin induced dyskinesias, including chorea, dysto and asterixis, similar to those induced by phenothiazine and other neuroleptic drugs.

A predominantly sensory peripheral polyneuropathy has been observed in patient long-term phenytoin therapy.

Gastrointestinal System: Nausea, vomiting, constipation, toxic hepatitis and liver

Integumentary System: Dermatological manifestations sometimes accompanied b included scarlatiniform or morbilliform rashes. A morbilliform rash (measles-like) i common; other types of dermatitis are seen more rarely. Other more serious forms be fatal have included bullous, exfoliative or purpuric dermatitis, lupus erythematosu Johnson syndrome, and toxic epidermal necrolysis (see Precautions).

Hemopoietic System: Hemopoietic complications, some fatal, have occasionally bee in association with administration of phenytoin. These have included thrombocytope penia, granulocytopenia, agranulocytosis, and pancytopenia with or without bone m pression. While macrocytosis and megaloblastic anemia have occurred, these conditi respond to folic acid therapy. Lymphadenopathy including benign lymph node hyperpl dolymphoma, lymphoma, and Hodgkin's Disease have been reported (see Warning

Connective Tissue System: Coarsening of the facial features, enlargement of the lip hyperplasia, hypertrichosis and Peyronie's Disease.

Cardiovascular: Periarteritis nodosa.

Immunologic: Hypersensitivity syndrome (which may include, but is not limited to, such as arthralgias, eosinophilia, fever, liver dysfunction, lymphadenopathy or rash) lupus erythematosus, immunoglobulin abnormalities.

OVERDOSAGE: The lethal dose in children is not known. The lethal dose in adults is to be 2 to 5 grams. The initial symptoms are nystagmus, ataxia, and dysarthria. Othe tremor, hyperreflexia, lethargy, slurred speech, nausea, vomiting. The patient ma comatose and hypotensive. Death is due to respiratory and circulatory depression.

There are marked variations among individuals with respect to phenytoin plasma le toxicity may occur. Nystagmus, on lateral gaze, usually appears at 20 mcg/mL, at mcg/mL, dysarthria and lethargy appear when the plasma concentration is over 40 mc as high a concentration as 50 mcg/mL has been reported without evidence of toxicity. as 25 times the therapeutic dose has been taken to result in a serum concentratio mcg/mL with complete recovery.

Treatment: Treatment is nonspecific since there is no known antidote.

The adequacy of the respiratory and circulatory systems should be carefully obs appropriate supportive measures employed. Hemodialysis can be considered since is not completely bound to plasma proteins. Total exchange transfusion has been u treatment of severe intoxication in children.

In acute overdosage the possibility of other CNS depressants, including alcohol, borne in mind.

Caution – Federal law prohibits dispensing without prescription. 0

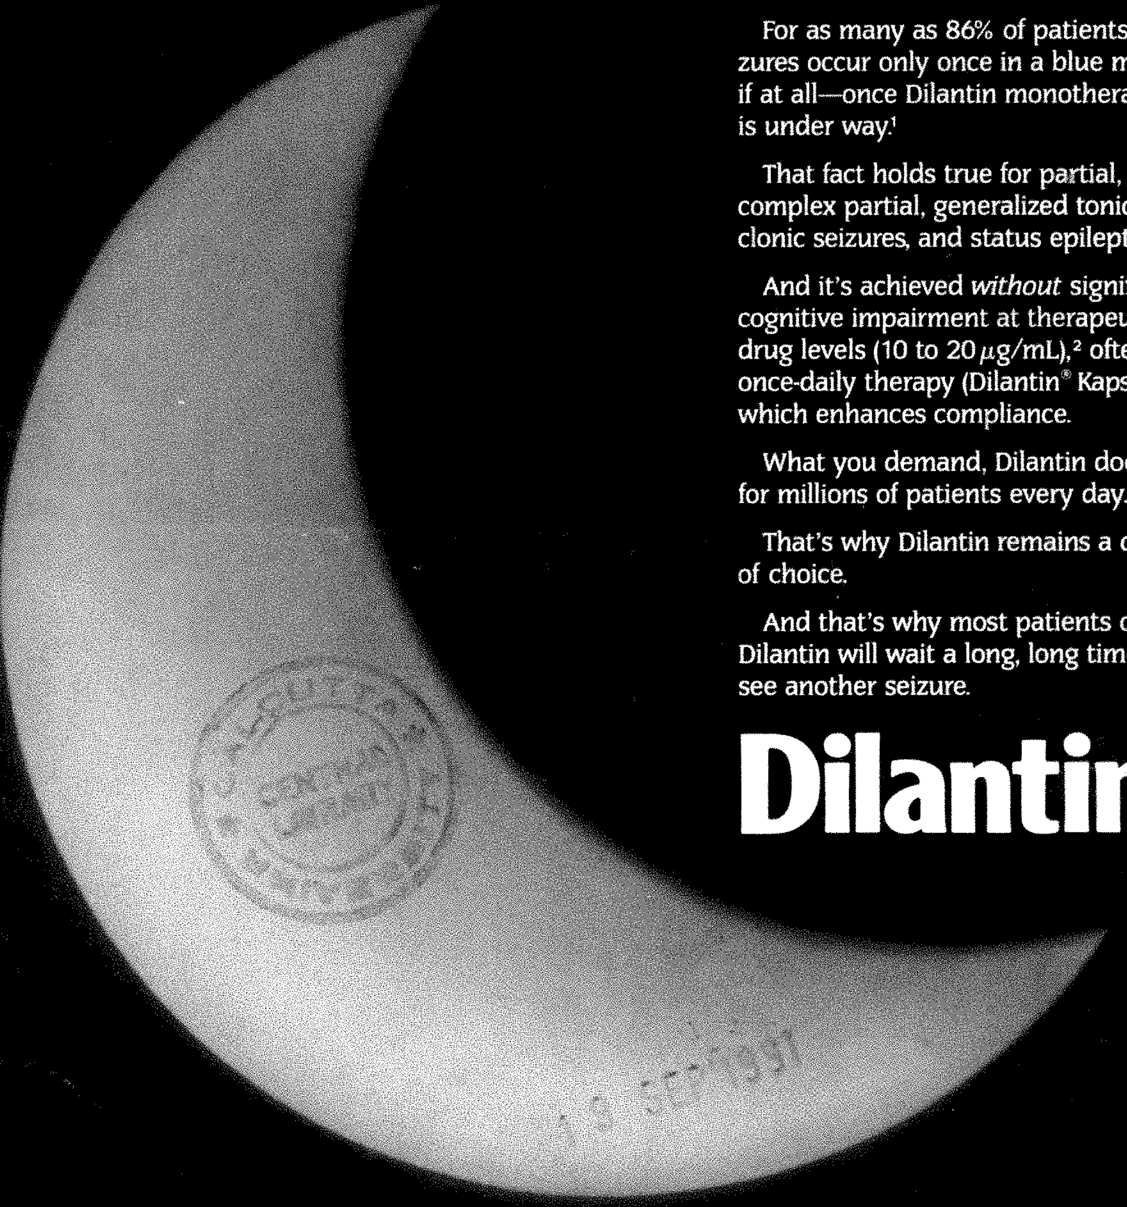
As rare as a seizure on Dilantin® (extended phenytoin sodium capsules, USP) 100 mg



19 SEP 1991

For as many as 86% of patients, seizures occur only once in a blue moon—if at all—once Dilantin monotherapy is under way.[1]

That fact holds true for partial, complex partial, generalized tonic-clonic seizures, and status epilepticus.

And it's achieved *without* significant cognitive impairment at therapeutic drug levels (10 to 20 μg/mL),[2] often *with* once-daily therapy (Dilantin® Kapseals®), which enhances compliance.

What you demand, Dilantin does—for millions of patients every day.

That's why Dilantin remains a drug of choice.

And that's why most patients on Dilantin will wait a long, long time to see another seizure.

Dilantin®

"Once in a blue moon" describes the phenomenon in which the moon appears as a brilliant blue. Seen worldwide following the volcanic eruption of Krakatoa in 1883, the blue moon occurs only when atmospheric cloud droplets, each less than 5 μm in diameter, form in abundance—an exceedingly rare event.[3]

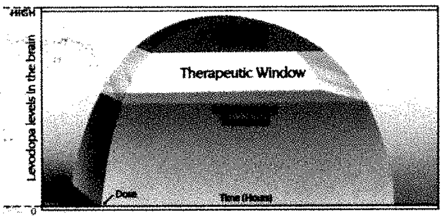
Sinemet®...for many patients with Parkinson's disease, the foundation of therapy for 15 years.

Sinemet®
(Carbidopa-Levodopa)
The Delicate Balance

Only Sinemet® helps you maintain the delicate balance needed for clinical control of Parkinson's disease.



Balancing Dopamine Replacement and Patient Response *Managing the symptoms of Parkinson's disease can be an ongoing balancing act, particularly as the disease progresses and the therapeutic window changes. By adjusting Sinemet® dosage strength and frequency according to patient needs, physicians can achieve the delicate balance needed between dopamine replacement and therapeutic response.*

The management of levodopa therapy in Parkinson's disease can be complex. It calls for a delicate balance between the relief of symptoms by the replacement of dopamine in the brain and the occurrence of side effects.

Dopamine replacement is the mainstay of therapy in Parkinson's disease. Only Sinemet® re-establishes dopamine levels in the brain.

But, too much or too little dopamine can affect the patient's quality of life. So dosage must be monitored and adjusted as the disease progresses, because the therapeutic window narrows over time.

Sinemet® provides you the flexibility needed to adjust dosage based on the individual patient's therapeutic window...by changing dosing frequency...dosage strength... or by changing the ratio between carbidopa and levodopa.

Nothing else helps you maintain the delicate balance needed to manage the signs and symptoms of Parkinson's disease like Sinemet®.

Because carbidopa permits more levodopa to reach the brain and, thus, more dopamine to be formed, dyskinesias may occur at lower doses and sooner with Sinemet® than with levodopa. The occurrence of dyskinesias may require dosage reduction. Please see a brief summary of prescribing information on the adjoining page.

For many patients with Parkinson's disease

Dosage Guidelines

Individualized dosage—a key to clinical success with Sinemet*

- Begin when symptoms first interfere with normal function
- Adjust as necessary to help maintain relief of symptoms

1

For initial therapy...Start with:

SINEMET 25-100

containing 25 mg carbidopa (anhydrous equivalent) and 100 mg levodopa

one tablet t.i.d.

If necessary, to control symptoms, dosage may be increased by one tablet every day or every other day until a dosage of eight tablets of Sinemet 25-100 a day is reached.

2

When it is evident that patients need more levodopa...Transfer to:

SINEMET 25-250

containing 25 mg carbidopa (anhydrous equivalent) and 250 mg levodopa

one tablet t.i.d.

If still more levodopa is necessary, dosage with Sinemet 25-250 may be increased by one-half to one tablet every day or every other day to a maximum of eight tablets a day.

3

When individualizing dosage...Titrate with:

SINEMET 10-100

containing 10 mg carbidopa (anhydrous equivalent) and 100 mg levodopa

or SINEMET 25-100

or SINEMET 25-250

The optimum daily dosage of Sinemet must be determined by careful titration in each patient. Tablets of the three strengths may be given separately or combined as needed to provide the optimum daily dosage.

For patients transferred from levodopa

DISCONTINUE LEVODOPA AT LEAST 8 HOURS BEFORE STARTING SINEMET.

The starting dose for Sinemet should provide about 25 percent of previous levodopa requirements. (Patients receiving less than 1500 mg of levodopa a day should be started on one tablet of Sinemet 25-100 t.i.d. or q.i.d.)

Sinemet®
(Carbidopa-Levodopa)

When SINEMET is to be given to patients who are being treated with levodopa, levodopa must be discontinued at least 8 hours before therapy with SINEMET is started. In order to reduce adverse reactions, it is necessary to individualize therapy. See the WARNINGS (below) and DOSAGE AND ADMINISTRATION sections in the Prescribing Information before initiating therapy.

Contraindications: MAO inhibitors and SINEMET should not be given concomitantly. MAO inhibitors must be discontinued at least 2 weeks prior to initiating therapy with SINEMET.

SINEMET is contraindicated in patients with known hypersensitivity to this drug and in narrow-angle glaucoma.

Because levodopa may activate a malignant melanoma, it should not be used in patients with suspicious, undiagnosed skin lesions or history of melanoma.

Warnings: Levodopa must be discontinued at least 8 hours before SINEMET is started. SINEMET should be substituted at a dosage that will provide approximately 25 percent of the previous levodopa dosage. (See DOSAGE AND ADMINISTRATION section of Prescribing Information.) Patients taking SINEMET should be instructed not to take additional levodopa unless prescribed.

As with levodopa, SINEMET may cause involuntary movements and mental disturbances. These reactions may be due to increased brain dopamine following administration of levodopa. All patients should be observed carefully for development of depression with concomitant suicidal tendencies. Treat with caution patients with past or current psychoses. *Because carbidopa permits more levodopa to reach the brain and, thus, more dopamine to be formed, dyskinesias may occur at lower dosages and sooner with* SINEMET *than with levodopa.* Occurrence of dyskinesias may require dosage reduction.

SINEMET should be administered cautiously to patients with severe cardiovascular or pulmonary disease, bronchial asthma, renal, hepatic or endocrine disease.

Exercise care in administering SINEMET, as with levodopa, to patients with history of myocardial infarction who have residual atrial, nodal, or ventricular arrhythmias. In such patients, cardiac function should be monitored with particular care during period of initial dosage adjustment, in a facility with provisions for intensive cardiac care.

As with levodopa, there is possibility of upper GI hemorrhage in patients with history of peptic ulcer.

A symptom complex resembling the neuroleptic malignant syndrome including muscular rigidity, elevated body temperature, mental changes, and increased serum creatine phosphokinase has been reported when antiparkinsonian agents were withdrawn abruptly. Therefore, patients should be observed carefully when the dosage of SINEMET is reduced abruptly or discontinued, especially if the patient is receiving neuroleptics.

Usage in Pregnancy and Lactation: Although effects of SINEMET on human pregnancy and lactation are unknown, both levodopa and combinations of carbidopa and levodopa have caused visceral and skeletal malformations in rabbits. Use of SINEMET in women of childbearing potential requires that anticipated benefits of the drug be weighed against possible hazards to mother and child. SINEMET should not be given to nursing mothers.

Usage in Children: Safety of SINEMET in patients under 18 has not been established.

Precautions: As with levodopa, periodic evaluations of hepatic, hematopoietic, cardiovascular, and renal function are recommended during extended therapy.

Patients with chronic wide-angle glaucoma may be treated cautiously with SINEMET provided intraocular pressure is well controlled and patient is monitored carefully for changes in intraocular pressure during therapy.

Laboratory Tests: Abnormalities in laboratory tests may include elevations of liver function tests such as alkaline phosphatase, SGOT (AST), SGPT (ALT), lactic dehydrogenase, and bilirubin. Abnormalities in protein-bound iodine, blood urea nitrogen, and positive Coombs test have also been reported. Commonly, levels of blood urea nitrogen, creatinine, and uric acid are lower during administration of SINEMET than with levodopa.

SINEMET may cause a false-positive reaction for urinary ketone bodies when a test tape is used for determination of ketonuria. This reaction will not be altered by boiling the urine specimen. False-negative tests may result with the use of glucose-oxidase methods of testing for glucosuria.

Drug Interactions: Caution should be exercised when the following drugs are administered concomitantly with SINEMET.

Symptomatic postural hypotension can occur when SINEMET is added to the treatment of a patient receiving antihypertensive drugs. Therefore, when therapy with SINEMET is started, dosage adjustment of the antihypertensive drug may be required. For patients receiving monoamine oxidase inhibitors, see CONTRAINDICATIONS (above).

There have been rare reports of adverse reactions, including hypertension and dyskinesia, resulting from the concomitant use of tricyclic antidepressants and SINEMET.

Phenothiazines and butyrophenones may reduce the therapeutic effects of levodopa. In addition, the beneficial effects of levodopa in Parkinson's disease have been reported to be reversed by phenytoin and papaverine. Patients taking these drugs with SINEMET should be carefully observed for loss of therapeutic response.

Adverse Reactions: Most common serious adverse reactions occurring with SINEMET are choreiform, dystonic, and other involuntary movements. Other serious adverse reactions are mental changes including paranoid ideation and psychotic episodes, depression with or without development of suicidal tendencies and dementia. Convulsions also have occurred; however, a causal relationship with SINEMET has not been established.

A common but less serious effect is nausea.

Less frequent adverse reactions are cardiac irregularities and/or palpitation, orthostatic hypotensive episodes, bradykinetic episodes (the "on-off" phenomenon), anorexia, vomiting, and dizziness.

Rarely, GI bleeding, development of duodenal ulcer, hypertension, phlebitis, hemolytic and non-hemolytic anemia, thrombocytopenia, leukopenia, and agranulocytosis have occurred.

Laboratory tests which have been reported to be abnormal are alkaline phosphatase, SGOT (AST), SGPT (ALT), lactic dehydrogenase, bilirubin, blood urea nitrogen, protein-bound iodine, and Coombs test.

Other adverse reactions that have been reported with levodopa are: *Nervous System*: ataxia, numbness, increased hand tremor, muscle twitching, muscle cramps, blepharospasm (which may be taken as an early sign of excess dosage, consideration of dosage reduction may be made at this time), trismus, activation of latent Horner's syndrome. *Psychiatric*: confusion, sleepiness, insomnia, nightmares, hallucinations, delusions, agitation, anxiety, euphoria. *Gastrointestinal*: dry mouth, bitter taste, sialorrhea, dysphagia, bruxism, hiccups, abdominal pain and distress, constipation, diarrhea, flatulence, burning sensation of tongue. *Metabolic*: weight gain or loss, edema. *Integumentary*: malignant melanoma (see also CONTRAINDICATIONS), flushing, increased sweating, dark sweat, skin rash, loss of hair. *Genitourinary*: urinary retention, urinary incontinence, dark urine, priapism. *Special Senses*: diplopia, blurred vision, dilated pupils, oculogyric crises. *Miscellaneous*: weakness, faintness, fatigue, headache, hoarseness, malaise, hot flashes, sense of stimulation, bizarre breathing patterns, neuroleptic malignant syndrome.

Overdosage: Management of acute overdosage with SINEMET is basically the same as management of acute overdosage with levodopa; however, pyridoxine is not effective in reversing the actions of SINEMET.

How Supplied: Tablets SINEMET 10-100, SINEMET 25-100, and SINEMET 25-250 are supplied in bottles of 100 and unit dose packages of 100.

Storage: Tablets SINEMET 10-100 and Tablets SINEMET 25-250 must be protected from light.

INDERAL® LA (propranolol HCl) Long Acting Capsules
BRIEF SUMMARY OF PRESCRIBING INFORMATION:
CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION.

CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first-degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS), unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned, the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (eg, chronic bronchitis, emphysema) – PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, eg, dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Use beta blockers with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia; other manifestations such as dizziness and sweating may not be significantly affected. Following insulin-induced hypoglycemia, propranolol may cause a delay in the recovery of blood glucose to normal levels.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism, thus abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol may change thyroid-function tests, increasing T_4 and reverse T_3, and decreasing T_3.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, tachycardia was replaced by severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS. GENERAL: Use with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

CLINICAL LABORATORY TESTS: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity resulting in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Caution should be exercised when patients receiving a beta blocker are administered a calcium-channel-blocking drug, especially intravenous verapamil, as both agents may depress myocardial contractility or atrioventricular conduction. On rare occasions, the concomitant intravenous use of a beta blocker and verapamil has resulted in serious adverse reactions, especially in patients with severe cardiomyopathy, congestive heart failure or recent myocardial infarction.

Aluminum hydroxide gel greatly reduces intestinal absorption of propranolol.

Ethanol slows the rate of absorption of propranolol.

Phenytoin, phenobarbitone, and *rifampin* accelerate propranolol clearance.

Chlorpromazine, when used concomitantly with propranolol, results in increased plasma levels of both drugs.

Antipyrine and *lidocaine* have reduced clearance when used concomitantly with propranolol.

Thyroxine may result in a lower than expected T_3 concentration when used concomitantly with propranolol.

Cimetidine decreases the hepatic metabolism of propranolol, delaying elimination and increasing blood levels.

Theophylline clearance is reduced when used concomitantly with propranolol.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: There was no evidence of significant drug-induced toxicity in rats or mice, employing doses up to 150 mg/kg/day over an 18-month period. There were no drug-related tumorigenic effects at any dosage levels. No impairment of fertility attributable to the drug was seen in animal reproductive studies.

PREGNANCY: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. Use during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS: INDERAL is excreted in human milk. Exercise caution when INDERAL is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: Bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Light-headedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; vivid dreams; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. For immediate formulations, fatigue, lethargy, and vivid dreams appear dose related.

Gastrointestinal: Nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: Pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm, and respiratory distress.

Respiratory: Bronchospasm.

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: Alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. The oculomucocutaneous reactions associated with practolol have not been reported with propranolol.

DOSAGE AND ADMINISTRATION: INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL Tablets to INDERAL LA Capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg-for-mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary, especially to maintain effectiveness at the end of the 24-hour dosing interval.

For management of hypertension, angina pectoris, migraine, and hypertrophic subaortic stenosis the dosage must be individualized. Usual initial dose is 80 mg once daily.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

PEDIATRIC DOSAGE – At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE. INDERAL is not significantly dialyzable. If ingestion is, or may have been, recent, evacuate gastric contents, taking care to prevent pulmonary aspiration.

BRADYCARDIA: Administer atropine (0.25 to 1.0 mg); if no response to vagal blockade, administer isoproterenol cautiously. CARDIAC FAILURE: digitalization and diuretics. HYPOTENSION: vasopressors, eg, levarterenol or epinephrine (there is evidence that epinephrine is the drug of choice). BRONCHOSPASM: administer isoproterenol and aminophylline.

The appearance of these capsules is a registered trademark of Ayerst Laboratories.

WYETH-AYERST LABORATORIES
Philadelphia, PA 19101

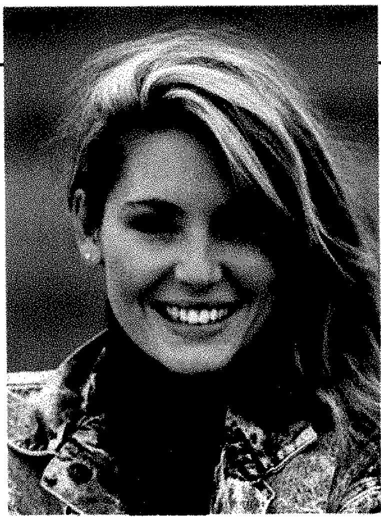
"Violent Passages" is a time-lapse portrayal by Louise Woodard depicting her own migraine headache sequence as she sees it. Her work focuses on the pain surrounding her eye and the confusion she feels as a result of the migraine.

with a daily dose of prevention.



Migraine. It's agonizing, debilitating, unpredictable. And abortive therapies often provide inadequate relief or cause troublesome side effects for your patients.

Proven qd prophylaxis at recommended doses.

Only INDERAL® LA provides once-daily preventive therapy— to significantly reduce both frequency and severity of common migraine. **Start with 80 mg/day and titrate to an effective dose — usually 160 to 240 mg once daily.**

Well-tolerated, long-term efficacy.

For patients whose day-to-day lives are undermined by anticipation of migraine, INDERAL LA can offer an improved sense of control. Because the only thing worse than the pain of migraine is the threat of it.

ONCE-DAILY
INDERAL® LA
(PROPRANOLOL HCl)
LONG ACTING CAPSULES
60, 80, 120, 160 mg

Another day without migraine.

Please see next page for brief summary of prescribing information.

INDERAL LA should not be used in the presence of congestive heart failure, sinus bradycardia, cardiogenic shock, heart block greater than first degree, and bronchial asthma.

Grand Rounds on Medical Malpractice

Build a strong foundation in the fundamentals of medical liability and risk management.

- *A primary resource book in medical liability and risk management*
- *Suitable for individual or group study*
- *AMA PRA Category 1 CME credit*

Each chapter includes a medical case scenario, discussion questions, a thorough exposition of the chapter topic, selected articles reprinted from the medical literature, and an annotated bibliography.

Grand Rounds was written by Francis X. Campion, MD, with the Risk Management Foundation of the Harvard Medical Institutions. The Harvard Medical School has incorporated *Grand Rounds* into its 1990-91 curriculum.

Order *Grand Rounds on Medical Malpractice* today. Call toll-free

From refill to refill... which carbamazepine will your patient get next?

TEGRETOL is indicated for children 6 years and older and adults

Because of the potential for serious hematologic adverse reactions, it is important that you become thoroughly familiar with the full Prescribing Information for TEGRETOL on the following page, especially the boxed warning.

CIBA–GEIGY

Prevent substitution when you prescribe Tegretol

Sign each prescription on the line that prevents substitution, or add the phrase required in your state to prevent substitution:

☐ Dispense As Written
☐ No Substitution
☐ Do Not Substitute
☐ Brand Necessary
☐ No Drug Product Selection
☐ May Not Substitute
☐ Medically Necessary

For your Medicaid patients...

To prevent substitution of TEGRETOL for your Medicaid patients, be sure to add the phrase "Brand Medically Necessary" on each prescription.

Tegretol®
carbamazepine USP

200 mg scored tablets
100 mg chewable tablets

...because there's no substitute for experience.

Tegretol® carbamazepine USP

Chewable Tablets of 100 mg—red-speckled, pink **Tablets of 200 mg—pink**

WARNING

APLASTIC ANEMIA AND AGRANULOCYTOSIS HAVE BEEN REPORTED IN ASSOCIATION WITH THE USE OF TEGRETOL DATA FROM A POPULATION-BASED CASE CONTROL STUDY DEMONSTRATE THAT THE RISK OF DEVELOPING THESE REACTIONS IS 5-8 TIMES GREATER THAN IN THE GENERAL POPULATION HOWEVER THE OVERALL RISK OF THESE REACTIONS IN THE UNTREATED GENERAL POPULATION IS LOW APPROXIMATELY SIX PATIENTS PER ONE MILLION POPULATION PER YEAR FOR AGRANULOCYTOSIS AND TWO PATIENTS PER ONE MILLION POPULATION PER YEAR FOR APLASTIC ANEMIA

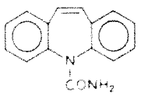
ALTHOUGH REPORTS OF TRANSIENT OR PERSISTENT DECREASED PLATELET OR WHITE BLOOD CELL COUNTS ARE NOT UNCOMMON IN ASSOCIATION WITH THE USE OF TEGRETOL DATA ARE NOT AVAILABLE TO ESTIMATE ACCURATELY THEIR INCIDENCE OR OUTCOME HOWEVER THE VAST MAJORITY OF THE CASES OF LEUKOPENIA HAVE NOT PROGRESSED TO THE MORE SERIOUS CONDITIONS OF APLASTIC ANEMIA OR AGRANULOCYTOSIS

BECAUSE OF THE VERY LOW INCIDENCE OF AGRANULOCYTOSIS AND APLASTIC ANEMIA THE VAST MAJORITY OF MINOR HEMATOLOGIC CHANGES OBSERVED IN MONITORING OF PATIENTS ON TEGRETOL ARE UNLIKELY TO SIGNAL THE OCCURRENCE OF EITHER ABNORMALITY NONETHELESS COMPLETE PRETREATMENT HEMATOLOGICAL TESTING SHOULD BE OBTAINED AS A BASELINE IF A PATIENT IN THE COURSE OF TREATMENT EXHIBITS LOW OR DECREASED WHITE BLOOD CELL OR PLATELET COUNTS. THE PATIENT SHOULD BE MONITORED CLOSELY DISCONTINUATION OF THE DRUG SHOULD BE CONSIDERED IF ANY EVIDENCE OF SIGNIFICANT BONE MARROW DEPRESSION DEVELOPS

Before prescribing Tegretol, the physician should be thoroughly familiar with the details of this prescribing information, particularly regarding use with other drugs, especially those which accentuate toxicity potential.

DESCRIPTION

Tegretol carbamazepine USP is an anticonvulsant and specific analgesic for trigeminal neuralgia available as chewable tablets of 100 mg and tablets of 200 mg for oral administration Its chemical name is 5H-dibenz [b f]azepine-5-carboxamide and its structural formula is



Carbamazepine USP is a white to off-white powder practically insoluble in water and soluble in alcohol and in acetone Its molecular weight is 236 27

Inactive Ingredients Colloidal silicon dioxide FD&C Red No 3 (chewable tablets only), FD&C Red No 40 (200-mg tablets only) flavoring (chewable tablets only) gelatin, glycerin magnesium stearate sodium starch glycolate (chewable tablets only), starch stearic acid, and sucrose (chewable tablets only)

CLINICAL PHARMACOLOGY

In controlled clinical trials Tegretol has been shown to be effective in the treatment of psychomotor and grand mal seizures, as well as trigeminal neuralgia

It has demonstrated anticonvulsant properties in rats and mice with electrically and chemically induced seizures It appears to act by reducing polysynaptic responses and blocking the posttetanic potentiation Tegretol greatly reduces or abolishes pain induced by stimulation of the infraorbital nerve in cats and rats It depresses thalamic potential and bulbar and polysynaptic reflexes, including the linguomandibular reflex in cats Tegretol is chemically unrelated to other anticonvulsants or other drugs used to control the pain of trigeminal neuralgia The mechanism of action remains unknown

Tegretol tablets are adequately absorbed after oral administration at a slower rate than a solution thus avoiding undesirably high peak concentrations Tegretol chewable tablets may produce higher peak levels than the same dose given as regular tablets Tegretol in blood is 76% bound to plasma proteins Plasma levels of Tegretol are variable and may range from 0 5-25 μg/ml, with no apparent relationship to the daily intake of the drug Usual adult therapeutic levels are between 4 and 12 μg/ml Following oral administration serum levels peak at 4 to 5 hours The CSF/serum ratio is 0 22 similar to the 22% unbound Tegretol in serum Because Tegretol may induce its own metabolism the half-life is also variable Initial half-life values range from 25-65 hours with 12-17 hours on repeated doses Tegretol is metabolized in the liver After oral administration of 14C-carbamazepine 72% of the administered radioactivity was found in the urine and 28% in the feces This urinary radioactivity was composed largely of hydroxylated and conjugated metabolites with only 3% of unchanged Tegretol Transplacental passage of Tegretol is rapid (30 to 60 minutes) and the drug is accumulated in fetal tissues with higher levels found in liver and kidney than in brain and lungs

INDICATIONS AND USAGE

Epilepsy: Tegretol is indicated for use as an anticonvulsant drug Evidence supporting efficacy of Tegretol as an anticonvulsant was derived from active drug-controlled studies that enrolled patients with the following seizure types

1 Partial seizures with complex symptomatology (psychomotor temporal lobe) Patients with these seizures appear to show greater improvement than those with other types
2 Generalized tonic-clonic seizures (grand mal)
3 Mixed seizure patterns which include the above or other partial or generalized seizures

Absence seizures (petit mal) do not appear to be controlled by Tegretol (see PRECAUTIONS General)

Trigeminal Neuralgia: Tegretol is indicated in the treatment of the pain associated with true trigeminal neuralgia

Beneficial results have also been reported in glossopharyngeal neuralgia

This drug is not a simple analgesic and should not be used for the relief of trivial aches or pains

CONTRAINDICATIONS

Tegretol should not be used in patients with a history of previous bone marrow depression hypersensitivity to the drug or known sensitivity to any of the tricyclic compounds such as amitriptyline, desipramine, imipramine, protriptyline nortriptyline etc Likewise, on theoretical grounds its use with monoamine oxidase inhibitors is not recommended Before administration of Tegretol MAO inhibitors should be discontinued for a minimum of fourteen days or longer if the clinical situation permits

WARNINGS

Patients with a history of adverse hematologic reaction to any drug may be particularly at risk

Severe dermatologic reactions including toxic epidermal necrolysis (Lyell's syndrome) and Stevens-Johnson syndrome have been reported with Tegretol These reactions have been extremely rare However, a few fatalities have been reported

Tegretol has shown mild anticholinergic activity, therefore, patients with increased intraocular pressure should be closely observed during therapy

Because of the relationship of the drug to other tricyclic compounds the possibility of activation of a latent psychosis and in elderly patients of confusion or agitation should be borne in mind

PRECAUTIONS

General: Before initiating therapy a detailed history and physical examination should be made

Tegretol should be used with caution in patients with a mixed seizure disorder that includes atypical absence seizures since in these patients Tegretol has been associated with increased frequency of generalized convulsions (see INDICATIONS AND USAGE)

Therapy should be prescribed only after critical benefit-to-risk appraisal in patients with a history of cardiac, hepatic or renal damage adverse hematologic reaction to other drugs, or interrupted courses of therapy with Tegretol

Information for Patients: Patients should be made aware of the early toxic signs and symptoms of a potential hematologic problem, such as fever sore throat ulcers in the mouth easy bruising petechial or purpuric hemorrhage and should be advised to report to the physician immediately if any such signs or symptoms appear

Since dizziness and drowsiness may occur, patients should be cautioned about the hazards of operating machinery or automobiles or engaging in other potentially dangerous tasks

Laboratory Tests: Complete pretreatment blood counts including platelets and possibly reticulocytes and serum iron, should be obtained as a baseline If a patient in the course of treatment exhibits low or decreased white blood cell or platelet counts the patient should be monitored closely. Discontinuation of the drug should be considered if any evidence of significant bone marrow depression develops

Baseline and periodic evaluations of liver function particularly in patients with a history of liver disease must be performed during treatment with this drug since liver damage may occur The drug should be discontinued immediately in cases of aggravated liver dysfunction or active liver disease

Baseline and periodic eye examinations including slit-lamp, funduscopy and tonometry are recommended since many phenothiazines and related drugs have been shown to cause eye changes

Baseline and periodic complete urinalysis and BUN determinations are recommended for patients treated with this agent because of observed renal dysfunction

Monitoring of blood levels (see CLINICAL PHARMACOLOGY) has increased the efficacy and safety of anticonvulsants This monitoring may be particularly useful in cases of dramatic increase in seizure frequency and for verification of compliance In addition measurement of drug serum levels may aid in determining the cause of toxicity when more than one medication is being used

Thyroid function tests have been reported to show decreased values with Tegretol administered alone

Hyponatremia has been reported in association with Tegretol use either alone or in combination with other drugs

Drug Interactions: The simultaneous administration of phenobarbital phenytoin or primidone or a combination of two, produces a marked lowering of serum levels of Tegretol The effect of valproic acid on Tegretol blood levels is not clearly established although an increase in the ratio of active 10 11-epoxide metabolite to parent compound is a consistent finding

The half-lives of phenytoin warfarin doxycycline and theophylline were significantly shortened when administered concurrently with Tegretol Haloperidol and valproic acid serum levels may be reduced when these drugs are administered with Tegretol The doses of these drugs may therefore have to be increased when Tegretol is added to the therapeutic regimen

Concomitant administration of Tegretol with erythromycin cimetidine propoxyphene isoniazid or calcium channel blockers has been reported to result in elevated plasma levels of carbamazepine resulting in toxicity in some cases Also concomitant administration of carbamazepine and lithium may increase the risk of neurotoxic side effects

Alterations of thyroid function have been reported in combination therapy with other anticonvulsant medications

Breakthrough bleeding has been reported among patients receiving concomitant oral contraceptives and their reliability may be adversely affected

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carbamazepine, when administered to Sprague-Dawley rats for two years in the diet at doses of 25 75 and 250 mg/kg/day resulted in a dose-related increase in the incidence of hepatocellular tumors in females and of benign interstitial cell adenomas in the testes of males

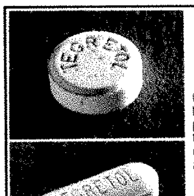
Carbamazepine must, therefore be considered to be carcinogenic in Sprague-Dawley rats Bacterial and mammalian mutagenicity studies using carbamazepine produced negative results The significance of these findings relative to the use of carbamazepine in humans is at present, unknown

Pregnancy Category C: Tegretol has been shown to have adverse effects in reproduction studies in rats when given orally in dosages 10-25 times the maximum human daily dosage of 1200 mg In rat teratology studies 2 of 135 offspring showed kinked ribs at 250 mg/kg and 4 of 119 offspring at 650 mg/kg showed other anomalies (cleft palate 1 talipes 1 anophthalmos 2) In reproduction studies in rats nursing offspring demonstrated a lack of weight gain and an unkempt appearance at a maternal dosage level of 200 mg/kg

There are no adequate and well-controlled studies in pregnant women Epidemiological data suggest that there may be an association between the use of carbamazepine during pregnancy and congenital malformations including spina bifida Tegretol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus

Retrospective case reviews suggest that compared with monotherapy, there may be a higher prevalence of teratogenic effects associated with the use of anticonvulsants in combination therapy Therefore monotherapy is recommended for pregnant women

It is important to note that anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life In individual cases where the severity and frequency of the seizure disorder are such that removal of medication does not pose a serious threat to the patient discontinuation of the drug may be considered prior to and during pregnancy although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus



Only TEGRETOL,
brand of carbamazepine,
provides the prescribing
flexibility of a 100-mg scored
chewable tablet, as well as
a 200-mg scored tablet

Labor and Delivery: The effect of Tegretol on human labor and delivery is unknown

Nursing Mothers: During lactation concentration of Tegretol in milk is approximately 60% of the maternal plasma concentration

Because of the potential for serious adverse reactions in nursing infants from carbamazepine a decision should be made whether to discontinue nursing or to discontinue the drug taking into account the importance of the drug to the mother

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established

ADVERSE REACTIONS

If adverse reactions are of such severity that the drug must be discontinued the physician must be aware that abrupt discontinuation of any anticonvulsant drug in a responsive epileptic patient may lead to seizures or even status epilepticus with its life-threatening hazards

The most severe adverse reactions have been observed in the hemopoietic system (see boxed WARNING) the skin and the cardiovascular system

The most frequently observed adverse reactions particularly during the initial phases of therapy are dizziness drowsiness unsteadiness nausea, and vomiting To minimize the possibility of such reactions therapy should be initiated at the low dosage recommended

The following additional adverse reactions have been reported

Hemopoietic System Aplastic anemia agranulocytosis pancytopenia bone marrow depression thrombocytopenia leukopenia leukocytosis eosinophilia acute intermittent porphyria

Skin Pruritic and erythematous rashes urticaria toxic epidermal necrolysis (Lyell's syndrome) (see WARNINGS) Stevens-Johnson syndrome (see WARNINGS) photosensitivity reactions, alterations in skin pigmentation exfoliative dermatitis erythema multiforme and nodosum, purpura, aggravation of disseminated lupus erythematosus alopecia and diaphoresis In certain cases discontinuation of therapy may be necessary

Cardiovascular System Congestive heart failure edema aggravation of hypertension hypotension syncope and collapse aggravation of coronary artery disease arrhythmias and AV block primary thrombophlebitis recurrence of thrombophlebitis and adenopathy or lymphadenopathy

Some of these cardiovascular complications have resulted in fatalities Myocardial infarction has been associated with other tricyclic compounds

Liver Abnormalities in liver function tests cholestatic and hepatocellular jaundice hepatitis

Respiratory System Pulmonary hypersensitivity characterized by fever dyspnea pneumonitis or pneumonia

Genitourinary System Urinary frequency acute urinary retention oliguria with elevated blood pressure azotemia renal failure and impotence Albuminuria glycosuria elevated BUN and microscopic deposits in the urine have also been reported

Testicular atrophy occurred in rats receiving Tegretol orally from 4 to 52 weeks at dosage levels of 50 to 400 mg/kg/day Additionally rats receiving Tegretol in the diet for two years at dosage levels of 25 75 and 250 mg/kg/day had a dose-related incidence of testicular atrophy and aspermatogenesis In dogs it produced a brownish discoloration presumably a metabolite in the urinary bladder at dosage levels of 50 mg/kg and higher Relevance of these findings to humans is unknown

Nervous System Dizziness drowsiness disturbances of coordination, confusion headache fatigue blurred vision visual hallucinations transient diplopia oculomotor disturbances nystagmus, speech disturbances, abnormal involuntary movements peripheral neuritis and paresthesias, depression with agitation talkativeness tinnitus and hyperacusis

There have been reports of associated paralysis and other symptoms of cerebral arterial insufficiency but the exact relationship of these reactions to the drug has not been established

Digestive System Nausea, vomiting gastric distress and abdominal pain diarrhea constipation anorexia and dryness of the mouth and pharynx including glossitis and stomatitis

Eyes Scattered punctate cortical lens opacities as well as conjunctivitis have been reported Although a direct causal relationship has not been established many phenothiazines and related drugs have been shown to cause eye changes

Musculoskeletal System Aching joints and muscles and leg cramps

Metabolism Fever and chills inappropriate antidiuretic hormone (ADH) secretion syndrome has been reported Cases of frank water intoxication with decreased serum sodium (hyponatremia) and confusion, have been reported in association with Tegretol use (see PRECAUTIONS Laboratory Tests)

Other Isolated cases of a lupus erythematosus-like syndrome have been reported There have been occasional reports of elevated levels of cholesterol HDL cholesterol and triglycerides in patients taking anticonvulsants

A case of aseptic meningitis accompanied by myoclonus and peripheral eosinophilia has been reported in a patient taking carbamazepine in combination with other medications The patient was successfully dechallenged, and the meningitis reappeared upon rechallenge with carbamazepine

DRUG ABUSE AND DEPENDENCE

No evidence of abuse potential has been associated with Tegretol nor is there evidence of psychological or physical dependence in humans

OVERDOSAGE

Acute Toxicity

Lowest known lethal dose adults, >60 g (39-year-old man) Highest known doses survived adults 30 g (31-year-old woman) children 10 g (6-year-old boy) small children 5 g (3-year-old girl)

Oral LD 50 in animals (mg/kg) mice, 1100-3750 rats, 3850-4025, rabbits 1500-2680, guinea pigs, 920

Signs and Symptoms

The first signs and symptoms appear after 1-3 hours Neuromuscular disturbances are the most prominent Cardiovascular disorders are generally milder and severe cardiac complications occur only when very high doses (>60 g) have been ingested

Respiration Irregular breathing respiratory depression

Cardiovascular System Tachycardia, hypotension or hypertension shock, conduction disorders

Nervous System and Muscles Impairment of consciousness ranging in severity to deep coma Convulsions especially in small children Motor restlessness muscular twitching tremor, athetoid movements opisthotonos, ataxia drowsiness dizziness mydriasis nystagmus adiadochokinesia ballism psychomotor disturbances dysmetria initial hyperreflexia followed by hyporeflexia

Gastrointestinal Tract Nausea, vomiting

Kidneys and Bladder Anuria or oliguria, urinary retention

Laboratory Findings Isolated instances of overdosage have included leukocytosis reduced leukocyte count glycosuria and acetonuria EEG may show dysrhythmias

Combined Poisoning When alcohol, tricyclic antidepressants barbiturates or hydantoins are taken at the same time the signs and symptoms of acute poisoning with Tegretol may be aggravated or modified

Treatment

The prognosis in cases of severe poisoning is critically dependent upon prompt elimination of the drug which may be achieved by inducing vomiting irrigating the stomach and by taking appropriate steps to diminish absorption If these measures cannot be implemented without risk on the spot the patient should be transferred at once to a hospital while ensuring that vital functions are safeguarded There is no specific antidote

Elimination of the Drug Induction of vomiting

Gastric lavage Even when more than 4 hours have elapsed following ingestion of the drug, the stomach should be repeatedly irrigated especially if the patient has also consumed alcohol

Measures to Reduce Absorption Activated charcoal, laxatives

Measures to Accelerate Elimination Forced diuresis

Dialysis is indicated only in severe poisoning associated with renal failure Replacement transfusion is indicated in severe poisoning in small children

Respiratory Depression Keep the airways free, resort, if necessary, to endotracheal intubation artificial respiration and administration of oxygen

Hypotension Shock Keep the patient's legs raised and administer a plasma expander If blood pressure fails to rise despite measures taken to increase plasma volume use of vasoactive substances should be considered

Convulsions Diazepam or barbiturates

Warning Diazepam or barbiturates may aggravate respiratory depression (especially in children), hypotension and coma However barbiturates should not be used if drugs that inhibit monoamine oxidase have also been taken by the patient either in overdosage or in recent therapy (within one week)

Surveillance Respiration cardiac function (ECG monitoring), blood pressure, body temperature pupillary reflexes and kidney and bladder function should be monitored for several days

Treatment of Blood Count Abnormalities If evidence of significant bone marrow depression develops the following recommendations are suggested (1) stop the drug (2) perform daily CBC platelet and reticulocyte counts (3) do a bone marrow aspiration and trephine biopsy immediately and repeat with sufficient frequency to monitor recovery

Special periodic studies might be helpful as follows (1) white cell and platelet antibodies (2) 59Fe—ferrokinetic studies, (3) peripheral blood cell typing, (4) cytogenetic studies on marrow and peripheral blood, (5) bone marrow culture studies for colony-forming units (6) hemoglobin electrophoresis for A_2 and F hemoglobin and (7) serum folic acid and B_{12} levels

A fully developed aplastic anemia will require appropriate intensive monitoring and therapy for which specialized consultation should be sought

DOSAGE AND ADMINISTRATION

Monitoring of blood levels has increased the efficacy and safety of anticonvulsants (see PRECAUTIONS Laboratory Tests) Dosage should be adjusted to the needs of the individual patient A low initial daily dosage with a gradual increase is advised As soon as adequate control is achieved the dosage may be reduced very gradually to the minimum effective level Tablets should be taken with meals

Epilepsy (see INDICATIONS AND USAGE)

Adults and children over 12 years of age—Initial: 200 mg b i d Increase at weekly intervals by adding up to 200 mg per day using a t i d or q i d regimen until the best response is obtained Dosage should generally not exceed 1000 mg daily in children 12 to 15 years of age and 1200 mg daily in patients above 15 years of age Doses up to 1600 mg daily have been used in adults in rare instances ***Maintenance***: Adjust dosage to the minimum effective level usually 800-1200 mg daily

Children 6-12 years of age—Initial: 100 mg b i d Increase at weekly intervals by adding 100 mg per day using a t i d or q i d regimen until the best response is obtained Dosage should generally not exceed 1000 mg ***Maintenance***: Adjust dosage to the minimum effective level usually 400-800 mg daily

Combination Therapy: Tegretol may be used alone or with other anticonvulsants When added to existing anticonvulsant therapy the drug should be added gradually while the other anticonvulsants are maintained or gradually decreased except phenytoin which may have to be increased (see PRECAUTIONS Drug Interactions and Pregnancy Category C)

Trigeminal Neuralgia (see INDICATIONS AND USAGE)

Initial: 100 mg b i d on the first day for a total daily dose of 200 mg This daily dose may be increased by up to 200 mg a day using increments of 100 mg every 12 hours only as needed to achieve freedom from pain Do not exceed 1200 mg daily

Maintenance: Control of pain can be maintained in most patients with 400 mg to 800 mg daily However some patients may be maintained on as little as 200 mg daily while others may require as much as 1200 mg daily At least once every 3 months throughout the treatment period attempts should be made to reduce the dose to the minimum effective level or even to discontinue the drug

HOW SUPPLIED

Chewable Tablets 100 mg—round red-speckled pink single-scored (imprinted Tegretol on one side and 52 twice on the scored side)

Bottles of 100	NDC 0028-0052-01
Unit Dose (blister pack)	
Box of 100 (strips of 10)	NDC 0028-0052-61

Tablets 200 mg—capsule-shaped, pink, single-scored (imprinted Tegretol on one side and 27 twice on the scored side)

Bottles of 100	NDC 0028-0027-01
Bottles of 1000	NDC 0028-0027-10
Gy-Pak®—One Unit 12 bottles—100 tablets each	NDC 0028-0027-65
Unit Dose (blister pack)	
Box of 100 (strips of 10)	NDC 0028-0027-61

Samples when available are identified by the word *SAMPLE* appearing on each tablet

Protect from moisture

Dispense in tight container (USP)

Also available as Tegretol suspension 100 mg/5 ml in 450 ml bottles

Printed in U S A C90-34 (Rev 6/90)

Books

Intervertebral Disk Disease: Causes, Diagnosis, Treatment, and Prophylaxis, ed 2, by Jurgen Kramer, 312 pp, New York, NY, Thieme Medical Publishers Inc, 1990.

This book, translated from the original German-language text, is one that is quite comprehensive, well written, and organized. The early chapters in the book are devoted to the basic sciences relevant to intervertebral disk disorders. The chapters on anatomy and physiology, biomechanics, and pathology are quite detailed, with very extensive scientific references. The chapter on the thoracic syndrome is very short, but the chapters on cervical and lumbar syndromes cover their subject matter well, with excellent descriptions of the clinical presentations related to specific pathologic processes. Newer imaging techniques in the evaluation of intervertebral disorders are described. Nonoperative and operative management and rehabilitation methods are well described. The concluding chapters deal with the psychological problems of patients with spine syndromes. The book concludes with a chapter on general rehabilitation and prevention. Most chapters are well illustrated with good diagrams and photographs. It makes for easy reading and is recommended for any physician who has to deal with problems related to the spine.

Donald P. K. Chan, MD
Rochester, NY

Diagnostic Tests in Neurology, by P. M. Matthews and D. L. Arnold, 372 pp, $39.95, New York, NY, Churchill Livingstone Inc, 1991.

Technological advances continue to improve our ability to study the healthy and diseased nervous system in the laboratory. The authors, along with four contributors, have written a small, soft-covered text devoted to diagnostic tests in neurology. This book is not intended as a textbook of neurology, and the authors point to the primacy of obtaining a history and performing an examination in neurologic diagnosis.

The book is divided into two sections. Section 1 is said to be at the level of a junior resident in neurology. It includes chapters dealing with lumbar puncture and cerebrospinal fluid, neuroradiology, ultrasound, evoked potentials, electromyography and electroencephalography, biopsies, and tests for hereditary metabolic diseases. These chapters begin with very elementary descriptions of each diagnostic test. Their coverage is somewhat uneven, but one can argue about the depth of knowledge of the various tests expected of a junior resident in neurology. Illustrations are included mainly in the chapters on imaging procedures. While appropriate, the figures are not as well reproduced as one might wish.

Section 2, "Diagnostic Approaches to Common Neurologic Problems," is organized in 10 chapters. Laboratory studies appropriate for the study of patients with seizures, coma, dementia, focal deficits, and other clinical categories are presented in more detail. Section 2 is replete with lists and tables, some quite exhaustive. The tables present the differential diagnosis of various neurologic conditions as perceived by the authors and suggest laboratory studies to arrive at the definitive diagnosis. Some lists are more detailed than others; many are quite current and useful, an example being the chapter that deals with the various coagulopathies.

One can argue with some of the titles: on page 52 one finds a section on "Cardiac Echocardiography."

Overall, this is a useful volume for the neurologic house officer and for the practicing neurologist.

A. F. Haerer, MD
Jackson, Miss

Neurological Complications of Cancer Treatment, by David A Rottenberg, 228 pp, $59.95, Stoneham, Mass, Butterworth Publishers Inc, 1991.

This is a fine, multiauthored monograph answering the need for a readily available reference on the neurological side effects of radiation and chemotherapy. The clinical presentation and pathophysiology of the various peripheral and central nervous system side effects of radiation and chemotherapy for malignancy are well covered. With the exception of an extensive chapter on arterial chemotherapy for central nervous system malignancy, an experimental modality limited by unacceptable side effects, the book appropriately covers all practical modalities of cancer therapy. There is a modicum of inevitable redundancy, which improves the value of each chapter as a single resource on the specific modality reviewed. The bibliographies are extensive.

This book is highly recommended for all physicians who are involved with the care of cancer patients.

Alexander Reeves, MD
Hanover, NH

The Cerebrospinal Fluid, edited by Robert M. Herndon and Roger A. Brumback, 306 pp, $110, Norwell, Mass, Kluwer Academic Publishers, 1989.

"A spinal tap! What for? We have the MRI, CT, EEG, EMG, SEP, MMPI, and I even did a history and physical. Just what can we learn from the CSF?" A familiar conversation with the house staff—just give them this book.

There has not been a good book on spinal fluid for many years. This likely reflects our distraction in high-technology brain imaging procedures. We have neglected one of the best diagnostic methods easily available to us.

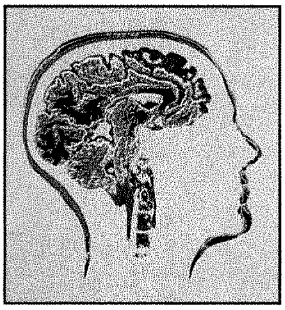
There are 11 chapters, with the major contributions by the two editors. They cover history, anatomy and physiology, production and flow, collection, injection, infections, proteins, immunology, cytology, and cytopathology. The authors are all experienced clinicians so that theory is introduced as it relates to clinical problems. The illustrations are excellent and the color plates are superb. The chapters on cytopathology illustrate the potential diagnostic possibilities offered by examination of the spinal fluid.

House staff should take time off from writing requisitions for various tests and read this to see what potential for diagnosis is the length of a needle away.

"Just get the spinal fluid, dammit!"

Robert J. Joynt, MD, PhD
Rochester, NY

THROUGH A CALCIUM-MODULATING MECHANISM OF ACTION



CEREBROSELECTIVE

NIMOTOP®

nimodipine/Miles

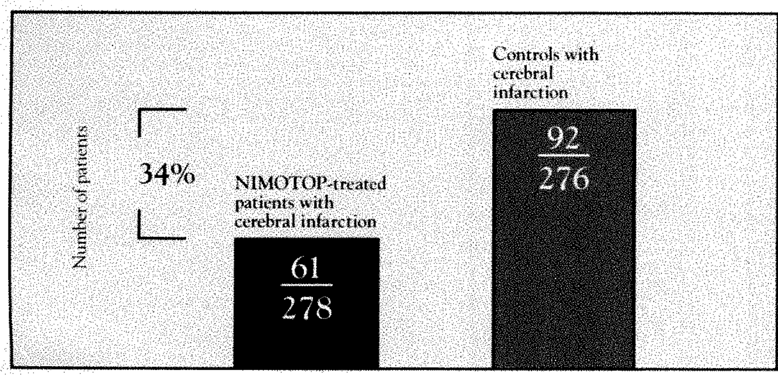
CAPSULES 30 mg

REDUCES INCIDENCE OF CEREBRAL INFARCTION IN PATIENTS FOLLOWING SUBARACHNOID HEMORRHAGE

In the largest study to date, NIMOTOP demonstrated a significant reduction in incidence of cerebral infarction[1]

- Twenty-two percent (61/278) of NIMOTOP-treated patients experienced cerebral infarction vs. 33% (92/276) of controls
- NIMOTOP reduced the incidence of cerebral infarction by 34%

Thirty-four percent reduction in incidence of cerebral infarction with NIMOTOP-treated patients vs. controls (n=554; p=0.003)[1]*



*90% of patients in this study were Hunt and Hess Grades I-III.

Dose: 60 mg (two 30 mg liquid-filled capsules) every 4 hours for 21 days commencing within 96 hours of SAH.

Adapted from Pickard, et al.[1]

NIMOTOP modulates calcium influx to promote cerebral perfusion, and may directly protect neurons[2-5]

"[In animals] The beneficial cytoprotective effect of nimodipine, probably related to normalization of calcium homeostasis and blood-brain barrier permeability after ischemia, may reflect both vascular and cellular sites of action."[6]

Lazarewicz JW, et al. *Stroke* 1989.

"[In humans] The data thus suggest that nimodipine neither prevents nor reverses cerebral vasospasm. Calcium channel blockers such as nimodipine may have an effect on cerebral arterioles that are below the limits of resolution of angiography. . . ."[1]

Pickard JD, et al. *Br Med J* 1989.

Please see references and Brief Summary of full prescribing information on next page.

MILES

CEREBROSELECTIVE
NIMOTOP®
nimodipine/Miles
CAPSULES 30 mg

NIMOTOP REDUCES THE INCIDENCE OF CEREBRAL INFARCTION FOLLOWING SUBARACHNOID HEMORRHAGE

BRIEF SUMMARY
NIMOTOP® (nimodipine/Miles) CAPSULES
For Oral Use

INDICATIONS AND USAGE

Nimotop® (nimodipine) is indicated for the improvement of neurological deficits due to spasm following subarachnoid hemorrhage from ruptured congenital intracranial aneurysms in patients who are in good neurological condition post-ictus (e.g. Hunt and Hess Grades I-III). Oral Nimotop® therapy should begin within 96 hours of the subarachnoid hemorrhage and continue for 21 days.

CONTRAINDICATIONS

None known.

PRECAUTIONS

General: Blood Pressure: Nimodipine has the hemodynamic effects expected of a calcium channel blocker, although they are generally not marked. In patients with subarachnoid hemorrhage given Nimotop® in clinical studies, about 5% were reported to have had lowering of the blood pressure and about 1% left the study because of this (not all could be attributed to nimodipine). Nevertheless, blood pressure should be carefully monitored during treatment with Nimotop® based on its known pharmacology and the known effects of calcium channel blockers.

Hepatic Disease: The metabolism of Nimotop® is decreased in patients with impaired hepatic function. Such patients should have their blood pressure and pulse rate monitored closely and should be given a lower dose (see Dosage and Administration).

Laboratory Test Interactions: None known.

Drug Interaction: It is possible that the cardiovascular action of other calcium channel blockers could be enhanced by the addition of Nimotop®.

In Europe, Nimotop® was observed to occasionally intensify the effect of antihypertensive compounds taken concomitantly by patients suffering from hypertension: this phenomenon was not observed in North American clinical trials.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study, higher incidences of adenocarcinoma of the uterus and Leydig-cell adenoma of the testes were observed in rats given a diet containing 1800 ppm nimodipine (equivalent to 91 to 121 mg/kg/day nimodipine) than in placebo controls. The differences were not statistically significant; however, the higher rates were well within historical control range for these tumors in the Wistar strain. Nimodipine was found not to be carcinogenic in a 91-week mouse study but the high dose of 1800 ppm nimodipine-in-feed (546 to 774 mg/kg/day) shortened the life expectancy of the animals. Mutagenic studies, including the Ames, micronucleus and dominant lethal tests were negative.

Nimodipine did not impair the fertility and general reproductive performance of male and female Wistar rats following oral doses of up to 30 mg/kg/day when administered daily for more than 10 weeks in the males and 3 weeks in the females prior to mating and continued to day 7 of pregnancy. This dose in a rat is about 4 times the equivalent clinical dose of 60 mg q4h in a 50 kg patient.

Pregnancy: Pregnancy Category C. Nimodipine has been shown to have a teratogenic effect in Himalayan rabbits. Incidences of malformations and stunted fetuses were increased at oral (by gavage) doses of 1 and 10 mg/kg/day administered from day 6 through day 18 of pregnancy but not at 3.0 mg/kg/day in one of two identical rabbit studies. In the second study an increased incidence of stunted fetuses was seen at 1.0 mg/kg/day but not at higher doses. Nimodipine was embryotoxic, causing resorption and stunted growth of fetuses, in Long Evans rats at 100 mg/kg/day administered by gavage from day 6 through day 15 of pregnancy. In two other rat studies, doses of 30 mg/kg/day nimodipine administered by gavage from day 16 of gestation and continued until sacrifice (day 20 of pregnancy or day 21 post partum) were associated with higher incidences of skeletal variation, stunted fetuses and stillbirths but no malformations. There are no adequate and well controlled studies in pregnant women to directly assess the effect on human fetuses. Nimodipine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Nimodipine and/or its metabolites have been shown to appear in rat milk at concentrations much higher than in maternal plasma. It is not known whether the drug is excreted in human milk. Because many drugs are excreted in human milk, nursing mothers are advised not to breast feed their babies when taking the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Adverse experiences were reported by 92 of 823 patients with subarachnoid hemorrhage (11.2%) who were given nimodipine. The most frequently reported adverse experience was decreased blood pressure in 4.4% of these patients. Twenty-nine of 479 (6.1%) placebo treated patients also reported adverse experiences. The events reported with a frequency greater than 1% are displayed below by dose.

DOSE q4h
Number of Patients (%)

	Nimodipine					Placebo
Sign/Symptom	**0.35 mg/kg (n = 82)**	**30 mg (n = 71)**	**60 mg (n = 494)**	**90 mg (n = 172)**	**120 mg (n = 4)**	**(n = 479)**
Decreased Blood Pressure	1 (1.2)	0	19 (3.8)	14 (8.1)	2 (50.0)	6 (1.2)
Abnormal Liver Function Test	1 (1.2)	0	2 (0.4)	1 (0.6)	0	7 (1.5)
Edema	0	0	2 (0.4)	2 (1.2)	0	3 (0.6)
Diarrhea	0	3 (4.2)	0	3 (1.7)	0	3 (0.6)
Rash	2 (2.4)	0	3 (0.6)	2 (1.2)	0	3 (0.6)
Headache	0	1 (1.4)	6 (1.2)	0	0	1 (0.2)
Gastrointestinal Symptoms	2 (2.4)	0	0	2 (1.2)	0	0
Nausea	1 (1.2)	1 (1.4)	6 (1.2)	1 (0.6)	0	0
Dyspnea	1 (1.2)	0	0	0	0	0
EKG Abnormalities	0	1 (1.4)	0	1 (0.6)	0	0
Tachycardia	0	1 (1.4)	0	0	0	0
Bradycardia	0	0	5 (1.0)	1 (0.6)	0	0
Muscle Pain/Cramp	0	1 (1.4)	1 (0.2)	1 (0.6)	0	0
Acne	0	1 (1.4)	0	0	0	0
Depression	0	1 (1.4)	0	0	0	0

There were no other adverse experiences reported by the patients who were given 0.35 mg/kg q4h, 30 mg q4h or 120 mg q4h. Adverse experiences with an incidence rate of less than 1% in the 60 mg q4h dose group were: hepatitis; itching; gastrointestinal hemorrhage; thrombocytopenia; anemia; palpitations; vomiting; flushing; diaphoresis; wheezing; phenytoin toxicity; lightheadedness; dizziness; rebound vasospasm; jaundice; hypertension; hematoma.

Adverse experiences with an incidence rate less than 1% in the 90 mg q4h dose group were: itching; gastrointestinal hemorrhage; thrombocytopenia; neurological deterioration; vomiting; diaphoresis; congestive heart failure; hyponatremia; decreasing platelet count; disseminated intravascular coagulation; deep vein thrombosis.

As can be seen from the table, side effects that appear related to nimodipine use based on increased incidence with higher dose or a higher rate compared to placebo control, included decreased blood pressure, edema and headaches which are known pharmacologic actions of calcium channel blockers. It must be noted, however, that SAH is frequently accompanied by alterations in consciousness which lead to an under reporting of adverse experiences. Patients who received nimodipine in clinical trials for other indications reported flushing (2.1%), headache (4.1%) and fluid retention (0.3%), typical responses to calcium channel blockers. As a calcium channel blocker, nimodipine may have the potential to exacerbate heart failure in susceptible patients or to interfere with A-V conduction, but these events were not observed.

No clinically significant effects on hematologic factors, renal or hepatic function or carbohydrate metabolism have been causally associated with oral nimodipine. Isolated cases of non-fasting elevated serum glucose levels (0.8%), elevated LDH levels (0.4%), decreased platelet counts (0.3%), elevated alkaline phosphatase levels (0.2%) and elevated SGPT levels (0.2%) have been reported rarely.

OVERDOSAGE

There have been no reports of overdosage from the oral administration of Nimotop®. Symptoms of overdosage would be expected to be related to cardiovascular effects such as excessive peripheral vasodilation with marked systemic hypotension. Clinically significant hypotension due to Nimotop® overdosage may require active cardiovascular support. Norepinephrine or dopamine may be helpful in restoring blood pressure. Since Nimotop® is highly protein-bound, dialysis is not likely to be of benefit.

DOSAGE AND ADMINISTRATION

Nimotop® is given orally in the form of ivory colored, soft gelatin 30 mg capsules for subarachnoid hemorrhage.

The oral dose is 60 mg (two 30 mg capsules) every 4 hours for 21 consecutive days. Oral Nimotop® therapy should commence within 96 hours of the subarachnoid hemorrhage.

If the capsule cannot be swallowed, e.g., at the time of surgery, or if the patient is unconscious, a hole should be made in both ends of the capsule with an 18 gauge needle, and the contents of the capsule extracted into a syringe. The contents should then be emptied into the patient's *in situ* naso-gastric tube and washed down the tube with 30 mL of normal saline (0.9%).

Patients with hepatic failure have substantially reduced clearance and approximately doubled C_{max}. Dosage should be reduced to 30 mg every 4 hours, with close monitoring of blood pressure and heart rate.

Letters to the Editor

Letters to the editor should be submitted as an original and two duplicates. They should be typewritten double-spaced on plain bond paper; they will be subject to editing. If they are prepared on a word processor, do not justify the right margin. A copyright transmittal letter signed by all authors must accompany this (see "Instructions for Authors").

Effect of Chemotherapy on Glioma Metabolism

To the Editor.—Rozental et al[1] reported the effect of chemotherapy on the uptake of fluorodeoxyglucose F18 into human gliomas determined by positron emission scanning. They confirmed previous reports that glucose uptake correlates with the histological degree of malignancy and, as had others, attributed the increased uptake to an intrinsically high aerobic glycolytic rate in tumors. Although it is true that most neoplastic cells have a higher rate of aerobic glycolysis (metabolism when fully oxygenated) than their nonneoplastic cells of origin[2]; it is doubtful that the metabolism of malignant gliomas is truly aerobic. Several years ago we noted that the metabolic enzyme profiles of several experimental neoplasms did suggest a high glycolytic capacity,[3] but that changes in glucose, lactate, and high-energy phosphates during ischemia in an experimental ependymoblastoma implanted in mouse brain indicated that the tumors functioned at less than adequate oxygen levels.[4,5] Indeed, the high levels of glycolytic enzymes may be partly an adaptation to a low oxygen environment.[6] In addition, the edema that is variably present may increase glucose metabolism in the absence of neoplastic cells.[7] The larger the neoplasm the greater the evidence of ischemia.[5] The high glucose uptake of malignant tumors may be largely dependent on their tendency to outgrow their supply of oxygen relative to that of glucose, inducing an increase in glucose uptake by the deregulation of glycolysis (Pasteur effect).[8,9] Microchemical measurements showing a gradient of metabolism, becoming more anaerobic with distance from supplying vessels,[8] support the importance of circulatory factors in determining the mode of metabolism.

Thymidine incorporation into cellular DNA, a marker of cell proliferation, was significantly greater in perivascular regions of a C6 neoplasm growing in mouse brain than in more poorly supplied deeper regions.[10] Following the administration of lomustine (CCNU), depressed thymidine incorporation recovered earlier in areas closer to capillaries than peripherally, although these regions had been exposed to higher concentrations of the agent. In monolayer culture, better oxygenated isolated C6 glioma cells were more vulnerable to nitrosourea damage than were confluent cells; vulnerability was inversely related to cell density.[11] Rozental et al[1] found increased fluorodeoxyglucose uptake (measured as tumor/white matter ratio) into several human gliomas 24 hours after chemotherapy and suggested that a direct metabolic effect may have occurred. Alternatively, a greater vulnerability to chemotherapy of cells infiltrating normal brain, close to vessels and with higher rates of proliferation and lower rates of "aerobic" glycolysis because of a better oxygen supply, could have contributed to the pattern of metabolic change found by positron emission tomographic scanning following treatment of the tumors by leaving a surviving cell population less well supplied with oxygen.

In Reply.—In his letter to the editor, Maker raises an interesting issue regarding our article "Glucose Uptake by Gliomas After Treatment."[1] Maker states that tumor cells in a well-oxygenated environment (closer to blood vessels) tend to be more vulnerable to chemotherapy. Thus, tumor cells in a relatively hypoxic environment would be more likely to survive treatment. Furthermore, the rate of glucose uptake by tumor cells increases and becomes deregulated with increasing hypoxia (increasing distance from blood vessels). Therefore, if hypoxic cell populations predominate following exposure to chemotherapy, glucose uptake would appear to increase relative to the baseline state.

This alternative explanation for the increase in glucose uptake observed after chemotherapy was only briefly considered in our discussion for several reasons. We stated that the phenomenon "... might have originated from the chemoresistant (ie, also hypoxic) subpopulation of cells, it could represent a mechanism for synchronization, release from growth arrest, and tumor overgrowth following ineffective chemotherapy." We felt that although a proportion of cells had surely accumulated a lethal amount of damage, a 24-hour interval from treatment was too short a period of time for the damaged cells to die. Even if such acute cell death occurred, one would expect a decrease from the baseline of *average* tumor metabolism simply because a group of metabolically active cells within the tumor volume had been eliminated. In other words, even though only hypoxic, "hypermetabolic" cells were left after the chemical debulking, fewer cells remained in the same volume. Otherwise, a collapse or structural rearrangement of the tumor must have taken place to account for an increase in glucose uptake within a region of interest of the same size taken from the same place on baseline and follow-up positron emission tomographic scans. Neither positron emission tomographic scans, computed tomographic scans, or magnetic resonance imaging give evidence of structural rearrangements within tumors at such an early interval following treatment.

It must also be pointed out that certain tumor models are capable of reenergizing (increasing their levels of nucleoside triphosphates and phosphocreatine) after treatment.[2] In that regard, at 4 days after treatment, a subcutaneous gliosarcoma reenergizes, shows a larger proportion of viable cells, and demonstrates a fivefold increase in interstitial space compared with the control tumor.[3] At this time, we can only speculate regarding the nature of our observation. It may reflect the first step in reenergization, increased energy requirements for repair, or incipient repopulation from a hypoxic cell pool (as Maker suggests).

We appreciate Maker's thought-provoking comments.

Post-Polio Fatigue Treated With Amantadine

To the Editor.—The post-polio syndrome (PPS) has received increased attention in recent years. This is a chronic slowly progressive condition with cardinal features consisting of weakness, atrophy, aches, cramps, and fatigue decades after the initial infection. Fatigue may be an incapacitating feature of this illness.

Amantadine has been found to be beneficial in the fatigue of multiple sclerosis.[1,2] The basis for this is uncertain. Amantadine also possesses antiviral and antiparkinsonian effects.

Average Daily Fatigue (Scale: 1 to 10)

Patient	Week 1	2	3*	4	5
1	5.4	7.2	5.3	4.2	5.0
2	7.8	7.0	6.5	7.1	6.5
3	5.7	7.6	1.8	2.2	. . .
4	4.4	3.2	3.0	3.0	2.3
5	5.4	5.4	5.6†	4.4	3.0
6	8.6	6.4‡	5.2	4.7	. . .
7	6.4	6.4	5.6	5.6	. . .
8	8.1	7.1	6.4	5.4§	. . .
9	7.3	7.1	6.6	7.1§	. . .

*Began treatment with amantadine.
†Upper respiratory illness.
‡Began treatment with amantadine after 1 week.
§Discontinued medication.

Over the last year an open study of amantadine (100 mg two times a day) given for the fatigue of PPS has been carried out in nine patients. All patients had PPS as diagnosed by a combination of accepted criteria, including history, physical examination, and electrodiagnostic testing, where applicable. The study used a 2-week control period with daily self-rating of fatigue on a subjective 0 (no fatigue) to 10 (incapacitating fatigue) scale. Treatment with amantadine (100 mg two times a day) was then begun. Eight of nine patients noted a subjective improvement in fatigue, and seven desired to stay on the medication (Table).

The degree of benefit is quite variable. Some patients appear to have little improvement, but still noted enough improvement to desire continued therapy (ie, patient 2). Others noted a dramatic difference (ie, patient 3). One patient left the study due to side effects and is not included in the Table. In one patient, the fatigue returned to prestudy baseline when the medication was discontinued after several months, and the beneficial effect of amantadine was reproduced when treatment was reinstituted.

This small study shows a trend toward reduction of fatigue in PPS with the use of amantadine. This may represent a significant advance in symptomatic treatment of this condition, as no other therapeutic modalities currently exist. A blinded placebo-controlled study would be appropriate based on these preliminary findings.

Machado-Joseph Disease or Not?

To the Editor.—Eto and coworkers[1] describe 12 patients with a hereditary ataxia they believe most closely resembles spinopontine atrophy as described by Boller and Segarra[2] in a large Rhode Island kindred, the family W, of English extraction. I have had contact with this family. One patient from the family actually appears in the literature twice, as patient 2 in the report on spinopontine atrophy by Pogacar et al,[3] and again as a patient with olivopontocerebellar atrophy in the writings of Huang and Plaitakis.[4] The distinctions between spinopontine atrophy and olivopontocerebellar atrophy seem slight indeed on clinical or pathologic grounds.

Eto et al[1] compare spinopontine atrophy to Machado-Joseph disease and note the many similarities. Machado-Joseph disease is distinctive primarily in its geographic source. Many hundreds of patients and nonaffected family members of Azorean lineage have been examined, and cultured cell lines established from those individuals who must surely represent a genetically homogeneous condition. Discovery of the gene seems only a matter of time (P. McLeod, personal communication). "Non-Azorean Machado-Joseph disease" is a term of little meaning until the genetic locus of Machado-Joseph disease, and of its non-Azorean wannabees, is worked out.

The family W, whether having olivopontocerebellar atrophy or spinopontine atrophy, represents a comparable opportunity for genetic analysis.

HEADACHE DESCRIBED

"Headache"– a personal interpretation of headache pain by John Crowley, a headache patient.

HEADACHE RELIEVED

Effectively treats the pain of muscle contraction headache as well as the anxiety and tension that magnify it

FIORINAL® WITH CODEINE CAPSULES Ⓒ III

(Each capsule contains: codeine phosphate 30 mg [Warning: May be habit-forming]; butalbital 50 mg [Warning: May be habit-forming], caffeine 40 mg; and aspirin 325 mg)

Potent relief of tension headache pain

Please see brief summary on following page.

SANDOZ

SANDOZ PHARMACEUTICALS CORPORATION
EAST HANOVER, NEW JERSEY 07936

5/91 Printed in U.S.A. FWC-1290-01

BRIEF SUMMARY: Please see package insert for full prescribing information.

FIORINAL® WITH CODEINE CIII CAPSULES

(Codeine phosphate USP, 30 mg [warning: may be habit forming]; butalbital USP, 50 mg [warning: may be habit forming]; caffeine USP, 40 mg; aspirin USP, 325 mg)

CAUTION: Federal law prohibits dispensing without prescription.

CONTRAINDICATIONS: Fiorinal® with Codeine is contraindicated under the following conditions:

1. Hypersensitivity or intolerance to aspirin, caffeine, butalbital or codeine.
2. Patients with a hemorrhagic diathesis (e.g., hemophilia, hypoprothrombinemia, von Willebrand's disease, the thrombocytopenias, thrombasthenia and other ill-defined hereditary platelet dysfunctions, severe vitamin K deficiency and severe liver damage.)
3. Patients with the syndrome of nasal polyps, angioedema and bronchospastic reactivity to aspirin or other nonsteroidal anti-inflammatory drugs. Anaphylactoid reactions have occurred in such patients.
4. Peptic ulcer or other serious gastrointestinal lesions.
5. Patients with porphyria.

WARNINGS: Therapeutic doses of aspirin can cause anaphylactic shock and other severe allergic reactions. It should be ascertained if the patient is allergic to aspirin, although a specific history of allergy may be lacking.

Significant bleeding can result from aspirin therapy in patients with peptic ulcer or other gastrointestinal lesions, and in patients with bleeding disorders.

Aspirin administered pre-operatively may prolong the bleeding time.

In the presence of head injury or other intracranial lesions, the respiratory depressant effects of codeine and other narcotics may be markedly enhanced, as well as their capacity for elevating cerebrospinal fluid pressure. Narcotics also produce other CNS depressant effects, such as drowsiness, that may further obscure the clinical course of patients with head injuries.

Codeine or other narcotics may obscure signs on which to judge the diagnosis or clinical course of patients with acute abdominal conditions.

Butalbital and codeine are both habit-forming and potentially abusable. Consequently, the extended use of Fiorinal® with Codeine is not recommended.

Results from epidemiologic studies indicate an association between aspirin and Reye Syndrome. Caution should be used in administering this product to children, including teenagers, with chicken pox or flu.

PRECAUTIONS: General: Fiorinal® with Codeine should be prescribed with caution for certain special-risk patients such as the elderly or debilitated, and those with severe impairment of renal or hepatic function, coagulation disorders, or head injuries.

Aspirin should be used with caution in patients on anticoagulant therapy and in patients with underlying hemostatic defects.

Precautions should be taken when administering salicylates to persons with known allergies. Hypersensitivity to aspirin is particularly likely in patients with nasal polyps, and relatively common in those with asthma.

Information for Patients: Patients should be informed that Fiorinal® with Codeine contains aspirin and should not be taken by patients with an aspirin allergy.

Fiorinal® with Codeine may impair the mental and/or physical abilities required for performance of potentially hazardous tasks such as driving a car or operating machinery. Such tasks should be avoided while taking Fiorinal® with Codeine.

Alcohol and other CNS depressants may produce an additive CNS depression when taken with Fiorinal® with Codeine, and should be avoided.

Codeine and butalbital may be habit-forming. Patients should take the drug only for as long as it is prescribed, in the amounts prescribed, and no more frequently than prescribed.

Laboratory Tests: In patients with severe hepatic or renal disease, effects of therapy should be monitored with serial liver and/or renal function tests.

Drug Interactions: The CNS effects of butalbital may be enhanced by monoamine oxidase (MAO) inhibitors.

In patients receiving concomitant corticosteroids and chronic use of aspirin, withdrawal of corticosteroids may result in salicylism because corticosteroids enhance renal clearance of salicylates and their withdrawal is followed by return to normal rates of renal clearance.

Fiorinal® with Codeine may enhance the effects of:

1. Oral anticoagulants, causing bleeding by inhibiting prothrombin formation in the liver and displacing anticoagulants from plasma protein binding sites.
2. Oral antidiabetic agents and insulin, causing hypoglycemia by contributing an additive effect, if dosage of Fiorinal® with Codeine exceeds maximum recommended daily dosage.
3. 6-mercaptopurine and methotrexate, causing bone marrow toxicity and blood dyscrasias by displacing these drugs from secondary binding sites, and, in the case of methotrexate, also reducing its excretion.
4. Non-steroidal anti-inflammatory agents, increasing the risk of peptic ulceration and bleeding by contributing additive effects.
5. Other narcotic analgesics, alcohol, general anesthetics, tranquilizers such as chlordiazepoxide, sedative-hypnotics, or other CNS depressants, causing increased CNS depression.

Fiorinal® with Codeine may diminish the effects of: Uricosuric agents such as probenecid and sulfinpyrazone, reducing their effectiveness in the treatment of gout. Aspirin competes with these agents for protein binding sites.

Drug/Laboratory Test Interactions

Aspirin: Aspirin may interfere with the following laboratory determinations in blood: serum amylase, fasting blood glucose, cholesterol, protein, serum glutamic-oxalacetic transaminase (SGOT), uric acid, prothrombin time and bleeding time. Aspirin may interfere with the following laboratory determinations in urine: glucose, 5-hydroxyindoleacetic acid, Gerhardt ketone, vanillylmandelic acid (VMA), uric acid, diacetic acid, and spectrophotometric detection of barbiturates.

Codeine: Codeine may increase serum amylase levels.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Adequate long-term studies have been conducted in mice and rats with aspirin, alone or in combination with other drugs, in which no evidence of carcinogenesis was seen. No adequate studies have been conducted in animals to determine whether aspirin has a potential for mutagenesis or impairment of fertility. No adequate studies have been conducted in animals to determine whether butalbital has a potential for carcinogenesis, mutagenesis, or impairment of fertility.

Usage in Pregnancy

Teratogenic Effects: Pregnancy Category C — Animal reproduction studies have not been conducted with Fiorinal® with Codeine. It is also not known whether Fiorinal® with Codeine can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Fiorinal® with Codeine should be given to a pregnant woman only when clearly needed.

Nonteratogenic Effects: Although Fiorinal® with Codeine was not implicated in the birth defect, a female infant was born with lissencephaly, pachygyria and heterotopic gray matter. The infant was born 8 weeks prematurely to a woman who had taken an average of 90 Fiorinal® with Codeine capsules each month from the first few days of pregnancy. The child's development was mildly delayed and from one year of age she had partial simple motor seizures.

Withdrawal seizures were reported in a two-day-old male infant whose mother had taken a butalbital-containing drug during the last 2 months of pregnancy. Butalbital was found in the infant's serum. The infant was given phenobarbital 5mg/kg, which was tapered without further seizure or other withdrawal symptoms.

Studies of aspirin use in pregnant women have not shown that aspirin increases the risk of abnormalities when administered during the first trimester of pregnancy. In controlled studies involving 41,337 pregnant women and their offspring, there was no evidence that aspirin taken during pregnancy caused stillbirth, neonatal death or reduced birth weight. In controlled studies of 50,282 pregnant women and their offspring, aspirin administration in moderate and heavy doses during the first four lunar months of pregnancy showed no teratogenic effect.

Reproduction studies have been performed in rabbits and rats at doses up to 150 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to codeine.

Therapeutic doses of aspirin in pregnant women close to term may cause bleeding in mother, fetus, or neonate. During the last 6 months of pregnancy, regular use of aspirin in high doses may prolong pregnancy and delivery.

Labor and Delivery: Ingestion of aspirin prior to delivery may prolong delivery or lead to bleeding in the mother or neonate. Use of codeine during labor may lead to respiratory depression in the neonate.

Nursing Mothers: Aspirin, caffeine, barbiturates and codeine are excreted in breast milk in small amounts, but the significance of their effects on nursing infants is not known. Because of potential for serious adverse reactions in nursing infants from Fiorinal® with Codeine, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children below the age of 12 have not been established.

ADVERSE REACTIONS: Commonly Observed: The most commonly reported adverse events associated with the use of Fiorinal® with Codeine and not reported at an equivalent incidence by placebo-treated patients were nausea and/or abdominal pain, drowsiness, and dizziness.

Associated with Treatment Discontinuation: Of the 382 patients treated with Fiorinal® with Codeine in controlled clinical trials, three (0.8%) discontinued treatment with Fiorinal® with Codeine because of adverse events. One patient each discontinued treatment for the following reasons: gastrointestinal upset; lightheadedness and heavy eyelids; and drowsiness and generalized tingling.

Incidence in Controlled Clinical Trials: The following table summarizes the incidence rates of the adverse events reported by at least 1% of the Fiorinal® with Codeine treated patients in controlled clinical trials comparing Fiorinal® with Codeine to placebo, and provides a comparison to the incidence rates reported by the placebo-treated patients.

The prescriber should be aware that these figures cannot be used to predict the incidence of side effects in the course of usual medical practice where patient characteristics and other factors differ from those that prevailed in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other clinical investigations involving different treatments, uses, and investigators.

Adverse Events Reported by at Least 1% of Fiorinal® with Codeine Treated Patients During Placebo Controlled Clinical Trials

	Incidence Rate of Adverse Events	
Body System/ Adverse Event	Fiorinal®/Codeine (N = 382)	Placebo (N = 377)
Central Nervous		
Drowsiness	2.4%	0.5%
Dizziness/Lightheadedness	2.6%	0.5%
Intoxicated Feeling	1.0%	0%
Gastrointestinal		
Nausea/Abdominal Pain	3.7%	0.8%

Other Adverse Events Reported During Controlled Clinical Trials: The listing that follows represents the proportion of the 382 patients exposed to Fiorinal® with Codeine while participating in the controlled clinical trials who reported, on at least one occasion, an adverse event of the type cited. All reported adverse events, except those already presented in the previous table, are included. It is important to emphasize that, although the adverse events reported did occur while the patient was receiving Fiorinal® with Codeine, the adverse events were not necessarily caused by Fiorinal® with Codeine.

Adverse events are classified by body system and frequency. "Frequent" is defined as an adverse event which occurred in at least 1/100 (1%) of the patients; all adverse events listed in the previous table are frequent. "Infrequent" is defined as an adverse event that occurred in less than 1/100 patients but at least 1/1000 patients. All adverse events tabulated below are classified as infrequent.

Central Nervous: headache, shaky feeling, tingling, agitation, fainting, fatigue, heavy eyelids, high energy, hot spells, numbness, and sluggishness.

Autonomic Nervous: dry mouth and hyperhidrosis.

Gastrointestinal: vomiting, difficulty swallowing, and heartburn.

Cardiovascular: tachycardia.

Musculoskeletal: leg pain and muscle fatigue.

Genitourinary: diuresis.

Miscellaneous: pruritus, fever, earache, nasal congestion, and tinnitus.

Voluntary reports of adverse drug events, temporally associated with Fiorinal® with Codeine, that have been received since market introduction and that were not reported in clinical trials by the patients treated with Fiorinal® with Codeine, are listed below. Many or most of these events may have no causal relationship with the drug and are listed according to body system.

Central Nervous: Abuse, addiction, anxiety, depression, disorientation, hallucination, hyperactivity, insomnia, libido decrease, nervousness, neuropathy, psychosis, sedation, sexual activity increase, slurred speech, twitching, unconsciousness, vertigo.

Autonomic Nervous: epistaxis, flushing, miosis, salivation.

Gastrointestinal: anorexia, appetite increased, constipation, diarrhea, esophagitis, gastroenteritis, gastrointestinal spasm, hiccup, mouth burning, pyloric ulcer.

Cardiovascular: chest pain, hypotensive reaction, palpitations, syncope.

Skin: erythema, erythema multiforme, exfoliative dermatitis, hives, rash, toxic epidermal necrolysis.

Urinary: kidney impairment, urinary difficulty.

Miscellaneous: allergic reaction, anaphylactic shock, cholangiocarcinoma, drug interaction with erythromycin (stomach upset), edema.

The following adverse drug events may be borne in mind as potential effects of the components of Fiorinal® with Codeine. Potential effects of high dosage are listed in the *OVERDOSAGE* section of this insert.

Aspirin: occult blood loss, hemolytic anemia, iron deficiency anemia, gastric distress, heartburn, nausea, peptic ulcer, prolonged bleeding time, acute airway obstruction, renal toxicity when taken in high doses for prolonged periods, impaired urate excretion, hepatitis.

Caffeine: cardiac stimulation, irritability, tremor, dependence, nephrotoxicity, hyperglycemia.

Codeine: nausea, vomiting, drowsiness, lightheadedness, constipation, pruritus.

DRUG ABUSE AND DEPENDENCE: Fiorinal® with Codeine is controlled by the Drug Enforcement Administration and is classified under Schedule III.

Codeine: Codeine can produce drug dependence of the morphine type and, therefore, has the potential for being abused. Psychological dependence, physical dependence, and tolerance may develop upon repeated administration and it should be prescribed and administered with the same degree of caution appropriate to the use of other oral narcotic medications.

Butalbital: *Barbiturates may be habit forming:* Tolerance, psychological dependence, and physical dependence may occur especially following prolonged use of high doses of barbiturates. The average daily dose for the barbiturate addict is usually about 1,500 mg. As tolerance to barbiturates develops, the amount needed to maintain the same level of intoxication increases; tolerance to a fatal dosage, however, does not increase more than two-fold. As this occurs, the margin between an intoxication dosage and fatal dosage becomes smaller. The lethal dose of a barbiturate is far less if alcohol is also ingested. Major withdrawal symptoms (convulsions and delirium) may occur within 16 hours and last up to 5 days after abrupt cessation of these drugs. Intensity of withdrawal symptoms gradually declines over a period of approximately 15 days. Treatment of barbiturate dependence consists of cautious and gradual withdrawal of the drug. Barbiturate-dependent patients can be withdrawn by using a number of different withdrawal regimens. One method involves initiating treatment at the patient's regular dosage level and gradually decreasing the daily dosage as tolerated by the patient.

OVERDOSAGE: The toxic effects of acute overdosage of Fiorinal® with Codeine capsules are attributable mainly to the barbiturate and codeine components, and, to a lesser extent, aspirin. Because toxic effects of caffeine occur in very high dosages only, the possibility of significant caffeine toxicity from Fiorinal® with Codeine overdosage is unlikely.

Signs and Symptoms: Symptoms attributable to *acute barbiturate poisoning* include drowsiness, confusion, and coma; respiratory depression; hypotension; shock. Symptoms attributable to *acute aspirin poisoning* include hyperpnea; acid-base disturbances with development of metabolic acidosis; vomiting and abdominal pain; tinnitus; hyperthermia; hypoprothrombinemia; restlessness; delirium; convulsions. *Acute caffeine poisoning* may cause insomnia, restlessness, tremor, and delirium; tachycardia and extrasystoles. Symptoms of *acute codeine poisoning* include the triad of: pinpoint pupils, marked depression of respiration, and loss of consciousness. Convulsions may occur.

Treatment: The following paragraphs describe one approach to the treatment of overdose with Fiorinal® with Codeine. However, because strategies for the management of an overdose continually evolve, consultation with a regional poison control center is strongly encouraged.

Treatment consists primarily of management of barbiturate intoxication, reversal of the effects of codeine, and the correction of the acid-base imbalance due to salicylism. Vomiting should be induced mechanically or with emetics in the conscious patient. Gastric lavage may be used if the pharyngeal and laryngeal reflexes are present and if less than 4 hours have elapsed since ingestion. A cuffed endotracheal tube should be inserted before gastric lavage of the unconscious patient and when necessary to provide assisted respiration. Diuresis, alkalinization of the urine, and correction of electrolyte disturbances should be accomplished through administration of intravenous fluids such as 1% sodium bicarbonate and 5% dextrose in water.

Meticulous attention should be given to maintaining adequate pulmonary ventilation. Correction of hypotension may require the administration of levarterenol bitartrate or phenylephrine hydrochloride by intravenous infusion. In severe cases of intoxication, peritoneal dialysis, hemodialysis, or exchange transfusion may be lifesaving. Hypoprothrombinemia should be treated with vitamin K, intravenously.

Methemoglobinemia over 30% should be treated with methylene blue by slow intravenous administration.

Naloxone, a narcotic antagonist, can reverse respiratory depression and coma associated with opioid overdose. Typically, a dose of 0.4 mg to 2 mg is given parenterally and may be repeated if an adequate response is not achieved. Since the duration of action of codeine may exceed that of the antagonist, the patient should be kept under continued surveillance and repeated doses of the antagonist should be administered as needed to maintain adequate respiration. A narcotic antagonist should not be administered in the absence of clinically significant respiratory or cardiovascular depression.

Toxic and Lethal Doses:

Butalbital: toxic dose 1.0 g (adult); lethal dose 2.0-5.0 g
Aspirin: toxic blood level greater than 30 mg/100 mL; lethal dose 10-30 g (adult)
Caffeine: toxic dose greater than 1.0 g; lethal dose unknown
Codeine: lethal dose 0.5-1.0 g (adult)

PERMAX®
pergolide mesylate

An added dimension
in the treatment of
Parkinson's disease

An adjunct to levodopa/carbidopa in the management of patients with Parkinson's disease

- The first dopamine agonist indicated for Parkinson's disease with activity at both D_1 and D_2 receptors
- 10 to 1,000 times more potent than bromocriptine on a milligram-per-milligram basis
- Improves patients' functioning in activities of daily living, relieves signs and symptoms, and reduces "off" time
- May allow a significant reduction in levodopa dosage
- Most common adverse events were dyskinesia, nausea, dizziness, and hallucinations
- Hypotension may occur, especially early in the course of therapy
- Stepwise titration without regard to meals
- Available in 0.05-mg, 0.25-mg, and 1-mg scored tablets

Permax*

pergolide mesylate

Brief Summary. Consult the package insert for complete prescribing information.

Indications and Usage: Permax is indicated as adjunctive treatment to levodopa/carbidopa in the management of the signs and symptoms of Parkinson's disease.

Evidence to support the efficacy of pergolide mesylate as an antiparkinsonian adjunct was obtained in a multicenter study enrolling 376 patients with mild to moderate Parkinson's disease who were intolerant to levodopa/carbidopa as manifested by moderate to severe dyskinesia and/or on-off phenomena. On average, the sample of patients evaluated had been on levodopa/carbidopa for 3.9 years (range, two days to 16.8 years). The administration of pergolide mesylate permitted a 5% to 30% reduction in the daily dose of levodopa. On average, these patients treated with pergolide mesylate maintained an equivalent or better clinical status than they exhibited at baseline.

Contraindications: Pergolide mesylate is contraindicated in patients who are hypersensitive to this drug or other ergot derivatives.

Warnings: *Symptomatic Hypotension*—In clinical trials, approximately 10% of patients taking pergolide mesylate with levodopa vs 7% taking placebo with levodopa experienced symptomatic orthostatic and/or sustained hypotension, especially during initial treatment. With gradual dosage titration, tolerance to the hypotension usually develops. It is, therefore, important to warn patients of the risk, to begin therapy with low doses, and to increase the dosage in carefully adjusted increments over a period of three to four weeks.

Hallucinosis—In controlled trials, pergolide mesylate with levodopa caused hallucinosis in about 14% of patients as opposed to 3% taking placebo with levodopa. This was of sufficient severity to cause discontinuation of treatment in about 3% of those enrolled; tolerance to this untoward effect was not observed.

Fatalities—In the placebo-controlled trial, two of 187 patients treated with placebo died as compared with one of 189 patients treated with pergolide mesylate. Of the 2,299 patients treated with pergolide mesylate in premarketing studies evaluated as of October 1988, 143 died while on the drug or shortly after discontinuing the drug. The patient population under evaluation was elderly, ill, and at high risk for death. It seems unlikely that pergolide mesylate played any role in these deaths, but the possibility that pergolide shortens survival of patients cannot be excluded with absolute certainty.

In particular, a case-by-case review of the clinical course of the patients who died failed to disclose any unique set of signs, symptoms, or laboratory results that would suggest that treatment with pergolide caused their deaths. Sixty-eight percent (68%) of the patients who died were 65 years of age or over. No death (other than a suicide) occurred within the first month of treatment; most of the patients who died had been on pergolide for years. A relative frequency of the causes of death by organ system are: pulmonary failure/pneumonia, 35%; cardiovascular, 30%; cancer, 11%; unknown, 8.4%; infection, 3.5%; extrapyramidal syndrome, 3.5%; stroke, 2.1%; dysphagia, 2.1%; injury, 1.4%; suicide, 1.4%; dehydration, 0.7%; glomerulonephritis, 0.7%.

Precautions: *General*—Caution should be exercised when administering pergolide mesylate to patients prone to cardiac dysrhythmias.

In a study comparing pergolide mesylate and placebo, patients taking pergolide mesylate were found to have significantly more episodes of atrial premature contractions (APCs) and sinus tachycardia.

The use of pergolide mesylate in patients on levodopa may cause and/or exacerbate preexisting states of confusion and hallucinations (*see* Warnings). Also, the abrupt discontinuation of pergolide mesylate in patients receiving it chronically as an adjunct to levodopa may precipitate the onset of hallucinations and confusion; these may occur within a span of several days. Discontinuation of pergolide should be undertaken gradually whenever possible, even if the patient is to remain on levodopa.

The administration of pergolide mesylate to patients receiving levodopa may cause and/or exacerbate preexisting dyskinesia.

Information for Patients—Patients and their families should be informed of the common adverse consequences of the use of pergolide mesylate (*see* Adverse Reactions) and the risk of hypotension (*see* Warnings).

Patients should be advised to notify their physician if they become pregnant or intend to become pregnant during therapy.

Patients should be advised to notify their physician if they are breast feeding an infant.

Laboratory Tests—No specific laboratory tests are deemed essential for the management of patients on Permax. Periodic routine evaluation of all patients, however, is appropriate.

Drug Interactions—Dopamine antagonists, such as the neuroleptics (phenothiazines, butyrophenones, thioxanthines) or metoclopramide, ordinarily should not be administered concurrently with Permax (a dopamine agonist); these agents may diminish the effectiveness of Permax.

Because pergolide mesylate is approximately 90% associated with plasma proteins, caution should be exercised if pergolide mesylate is coadministered with other drugs known to affect protein binding.

Carcinogenesis, Mutagenesis, and Impairment of Fertility—A two-year carcinogenicity study was conducted in mice using dietary levels of pergolide mesylate equivalent to oral doses of 0.6, 3.7, and 36.4 mg/kg/day in males and 0.6, 4.4, and 40.8 mg/kg/day in females. A two-year study in rats was conducted using dietary levels equivalent to oral doses of 0.04, 0.18, and 0.88 mg/kg/day in males and 0.05, 0.28, and 1.42 mg/kg/day in females. The highest doses tested in the mice and rats were approximately 340 and 12 times the maximum human oral dose administered in controlled clinical trials (6 mg/day equivalent to 0.12 mg/kg/day).

A low incidence of uterine neoplasms occurred in both rats and mice. Endometrial adenomas and carcinomas were observed in rats. Endometrial sarcomas were observed in mice. The occurrence of these neoplasms is probably attributable to the high estrogen/progesterone ratio which would occur in rodents as a result of the prolactin-inhibiting action of pergolide mesylate. The endocrine mechanisms believed to be involved in the rodents are not present in humans. However, even though there is no known correlation between uterine malignancies occurring in pergolide-treated rodents and human risk, there are no human data to substantiate this conclusion.

Pergolide mesylate was evaluated for mutagenic potential in a battery of tests that included an Ames bacterial mutation assay, a DNA repair assay in cultured rat hepatocytes, a point-mutation assay in cultured L5178Y cells, and a determination of chromosome alteration in bone marrow cells of Chinese hamsters. A weak mutagenic response was noted in the in vitro mammalian cell-point-mutation assay using L5178Y cells only after metabolic activation with rat liver microsomes. No mutagenic effects were obtained in the two other in vitro assays and in the in vivo assay. The relevance of these findings to humans is unknown.

A fertility study in male and female mice showed that fertility was maintained at 0.6 and 1.7 mg/kg/day but decreased at 5.6 mg/kg/day. Prolactin has been reported to be involved in stimulating and maintaining progesterone levels required for implantation in mice and, therefore, the impaired fertility at high dose may occur because of depressed prolactin levels.

Usage in Pregnancy—Pregnancy Category B—Reproduction studies were conducted in mice at doses of 5, 16, and 45 mg/kg/day and in rabbits at doses of 2, 6, and 16 mg/kg/day. The highest doses tested in mice and rabbits were 375 and 133 times the 6 mg/day maximum human dose administered in controlled clinical trials. In these studies, there was no evidence of harm to the fetus due to pergolide mesylate.

There are, however, no adequate and well-controlled studies in pregnant women. Among women who received pergolide mesylate for endocrine disorders in premarketing studies, there were 33 pregnancies that resulted in healthy babies and four pregnancies that resulted in congenital abnormalities (two major, two minor); a causal relationship has not been established. Because human data are limited and because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—It is not known whether this drug is excreted in human milk. The pharmacologic action of pergolide mesylate suggests that it may interfere with lactation. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions to pergolide mesylate in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use—Safety and effectiveness in children have not been established.

Adverse Reactions: *Commonly Observed*—In premarketing clinical trials, the most commonly observed adverse events associated with use of pergolide mesylate which were not seen at an equivalent incidence among placebo-treated patients were: nervous system complaints, including dyskinesia, hallucinations, somnolence, insomnia; digestive complaints, including nausea, constipation, diarrhea, dyspepsia; and respiratory system complaints, including rhinitis.

Associated With Discontinuation of Treatment—Twenty-seven percent (27%) of approximately 1,200 patients receiving pergolide mesylate for treatment of Parkinson's disease in premarketing clinical trials in the US and Canada discontinued treatment due to adverse events. The events most commonly causing discontinuation were related to the nervous system (15.5%), primarily hallucinations (7.8%) and confusion (1.8%).

Fatalities—*See* Warnings.

Incidence in Controlled Clinical Trials—The table that follows enumerates adverse events that occurred at a frequency of 1% or more among patients taking pergolide mesylate who participated in the premarketing controlled clinical trials comparing pergolide mesylate with placebo. In a double-blind, controlled study of six months' duration, patients with Parkinson's disease were continued on levodopa/carbidopa and were randomly assigned to receive either pergolide mesylate or placebo as additional therapy.

The prescriber should be aware that these figures cannot be used to predict the incidence of side effects in the course of usual medical practice where patient characteristics and other factors differ from those which prevailed in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other clinical investigations involving different treatments, uses, and investigators. The cited figures, however, do provide the prescribing physician with some basis for estimating the relative contribution of drug and nondrug factors to the side-effect incidence rate in the population studied.

Incidence of Treatment-Emergent Adverse Experiences in the Placebo-Controlled Clinical Trial

	Percentage of Patients Reporting Events	
Body System/ Adverse Event*	Pergolide Mesylate N=189	Placebo N=187
Body as a Whole		
Pain	7.0	2.1
Abdominal pain	5.8	2.1
Injury, accident	5.8	7.0

*Events reported by at least 1% of patients receiving pergolide mesylate are included.

Events Observed During the Premarketing Evaluation of Permax—This section reports event frequencies evaluated as of October 1988 for adverse events ocurring in a group of approximately 1,800 patients who took multiple doses of pergolide mesylate. The conditions and duration of exposure to pergolide mesylate varied greatly, involving well-controlled studies as well as experience in open and uncontrolled clinical settings. In the absence of appropriate controls in some of the studies, a causal relationship between these events and treatment with pergolide mesylate cannot be determined.

The following enumeration by organ system describes events in terms of their relative frequency of reporting in the data base. Events of major clinical importance are also described in the Warnings and Precautions sections.

The following definitions of frequency are used: frequent adverse events are defined as those occurring in at least 1/100 patients; infrequent adverse events are those occurring in 1/100 to 1/1,000 patients; rare events are those occurring in fewer than 1/1,000 patients.

Body as a Whole—*Frequent:* headache, asthenia, accidental injury, abdominal pain, chest pain, back pain, flu syndrome, neck pain, fever; *Infrequent:* facial edema, chills, enlarged abdomen, malaise, neoplasm, hernia, pelvic pain, sepsis, cellulitis, moniliasis, abscess, jaw pain, hypothermia; *Rare:* acute abdominal syndrome, LE syndrome.

Cardiovascular System—*Frequent:* postural hypotension, syncope, hypertension, palpitations, vasodilatations, congestive heart failure; *Infrequent:* myocardial infarction, tachycardia, heart arrest, abnormal electrocardiogram, angina pectoris, thrombophlebitis, bradycardia, ventricular extrasystoles, cerebrovascular accident, ventricular tachycardia, cerebral ischemia, atrial fibrillation, varicose vein, pulmonary embolus, AV block, shock; *Rare:* vasculitis, pulmonary hypertension, pericarditis, migraine, heart block, cerebral hemorrhage.

Digestive System—*Frequent:* nausea, vomiting, dyspepsia, diarrhea, constipation, dry mouth, dysphagia; *Infrequent:* flatulence, abnormal liver function tests, increased appetite, salivary gland enlargement, thirst, gastroenteritis, gastritis, periodontal abscess, intestinal obstruction, nausea and vomiting, gingivitis, esophagitis, cholelithiasis, tooth caries, hepatitis, stomach ulcer, melena, hepatomegaly, hematemesis, eructation; *Rare:* sialadenitis, peptic ulcer, pancreatitis, jaundice, glossitis, fecal incontinence, duodenitis, colitis, cholecystitis, aphthous stomatitis, esophageal ulcer.

Endocrine System—*Infrequent:* hypothyroidism, adenoma, diabetes mellitus, ADH inappropriate; *Rare:* endocrine disorder, thyroid adenoma.

Hemic and Lymphatic System—*Frequent:* anemia; *Infrequent:* leukopenia, lymphadenopathy, leukocytosis, thrombocytopenia, petechia, megaloblastic anemia, cyanosis; *Rare:* purpura, lymphocytosis, eosinophilia, thrombocythemia, acute lymphoblastic leukemia, polycythemia, splenomegaly.

Metabolic and Nutritional System—*Frequent:* peripheral edema, weight loss, weight gain; *Infrequent:* dehydration, hypokalemia, hypoglycemia, iron deficiency anemia, hyperglycemia, gout, hypercholesteremia; *Rare:* electrolyte imbalance, cachexia, acidosis, hyperuricemia.

Musculoskeletal System—*Frequent:* twitching, myalgia, arthralgia; *Infrequent:* bone pain, tenosynovitis, myositis, bone sarcoma, arthritis; *Rare:* osteoporosis, muscle atrophy, osteomyelitis.

Nervous System—*Frequent:* dyskinesia, dizziness, hallucinations, confusion, somnolence, insomnia, dystonia, paresthesia, depression, anxiety, tremor, akinesia, extrapyramidal syndrome, abnormal gait, abnormal dreams, incoordination, psychosis, personality disorder, nervousness, choreoathetosis, amnesia, paranoid reaction, abnormal thinking; *Infrequent:* akathisia, neuropathy, neuralgia, hypertonia, delusion, convulsion, libido increased, euphoria, emotional lability, libido decreased, vertigo, myoclonus, coma, apathy, paralysis, neurosis, hyperkinesia, ataxia, acute brain syndrome, torticollis, meningitis, manic reaction, hypokinesia, hostility, agitation, hypotonia; *Rare:* stupor, neuritis, intracranial hypertension, hemiplegia, facial paralysis, brain edema, myelitis, hallucinations and confusion after abrupt discontinuation.

Respiratory System—*Frequent:* rhinitis, dyspnea, pneumonia, pharyngitis, cough increased; *Infrequent:* epistaxis, hiccup, sinusitis, bronchitis, voice alteration, hemoptysis, asthma, lung edema, pleural effusion, laryngitis, emphysema, apnea, hyperventilation; *Rare:* pneumothorax, lung fibrosis, larynx edema, hypoxia, hypoventilation, hemothorax, carcinoma of lung.

Skin and Appendages System—*Frequent:* sweating, rash; *Infrequent:* skin discoloration, pruritus, acne, skin ulcer, alopecia, dry skin, skin carcinoma, seborrhea, hirsutism, herpes simplex, eczema, fungal dermatitis, herpes zoster; *Rare:* vesiculobullous rash, subcutaneous nodule, skin nodule, skin benign neoplasm, lichenoid dermatitis.

Special Senses System—*Frequent:* diplopia; *Infrequent:* otitis media, conjunctivitis, tinnitus, deafness, taste perversion, ear pain, eye pain, glaucoma, eye hemorrhage, photophobia, visual field defect; *Rare:* blindness, cataract, retinal detachment, retinal vascular disorder.

Urogenital System—*Frequent:* urinary tract infection, urinary frequency, urinary incontinence, hematuria, dysmenorrhea; *Infrequent:* dysuria, breast pain, menorrhagia, impotence, cystitis, urinary retention, abortion, vaginal hemorrhage, vaginitis, priapism, kidney calculus, fibrocystic breast, lactation, uterine hemorrhage, urolithiasis, salpingitis, pyuria, metrorrhagia, menopause, kidney failure, breast carcinoma, cervical carcinoma; *Rare:* amenorrhea, bladder carcinoma, breast engorgement, epididymitis, hypogonadism, leukorrhea, nephrosis, pyelonephritis, urethral pain, uricaciduria, withdrawal bleeding.

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, Robert J. Joynt, MD, PhD, University of Rochester School of Medicine and Dentistry, 601 Elmwood Ave, Rochester, NY 14642. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

Cover Letter.—Designate one author as correspondent and provide a complete address and telephone number.

In the cover letter include (1) statement on authorship responsibility, (2) statement on financial disclosure, and (3) one of the two following statements on copyright *or* federal employment. Each of these three statements must be signed by *all* authors.

1. Authorship Responsibility.—"I certify that I have participated sufficiently in the conception and design of this work and the analysis of the data (when applicable), as well as the writing of this manuscript, to take public responsibility for it. I believe the manuscript represents valid work. I have reviewed the final version of the manuscript and approve it for publication. Neither this manuscript nor one with substantially similar content under my authorship has been published or is being considered for publication elsewhere, except as described in an attachment. Furthermore, I attest that I shall produce the data upon which the manuscript is based for examination by the editors or their assignees if requested."

2. Financial Disclosure.—"I certify that affiliations (if any) with or involvement in any organization or entity with a direct financial interest in the subject matter or materials discussed in the manuscript (eg, employment, consultancies, stock ownership, honoraria, expert testimony) are disclosed below."

Research or project support should be listed in an acknowledgment.

3a. Copyright Transfer.—"In consideration of the action of the American Medical Association (AMA) in reviewing and editing this submission, the author(s) undersigned hereby transfer(s) assign(s), or otherwise convey(s) all copyright ownership to the AMA in the event that such work is published by the AMA."

3b. Federal Employment.—"I was an employee of the US federal government when this work was investigated and prepared for publication; therefore, it is not protected by the Copyright Act and there is no copyright of which the ownership can be transferred."

We regret that transmittal letters not containing the preceding language signed by all authors of the submission will necessitate delay in review of the manuscript.

Editing.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit three high-quality copies of the entire manuscript. The copies will not be returned. The authors should keep the original manuscript for submission if accepted. The original manuscript (including references, legends, and tables) must be typed double-spaced on 21.6 × 27.9-cm 8½ × 11-in), heavy-duty white bond paper. Ample margins of at least 2.5 cm (1 in) should be provided. **If a word processor is used, do not justify right-hand margins.**

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, and the address to which requests for reprints should be sent.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author(s) (list all authors and/or editors up to six; if more than six, list the first three and "et al"), (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) year, (5) volume number, and (6) inclusive page numbers, in that order. References to books should include (1) author(s) (list all authors and/or editors up to six; if more than six, list the first three and "et al"), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. **The author is responsible for the accuracy and completeness of the references and for their correct text citation.**

SI Units.—Use Système International (SI) measurements throughout the manuscript. (See June 1986 issue of the ARCHIVES.)

Illustrations.—The illustrations originally submitted will not be returned. High-quality copies may be used. Original illustrations should be kept by the author for submission if the manuscript is accepted. Use only those illustrations that clarify and augment the text. If accepted, submit illustrations in triplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.7 × 7.3 cm (5 × 7 in).

Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the ARCHIVES' contribution, the author's share is $400 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the ARCHIVES after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9-cm (8½ × 11-in) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

EIGHTEENTH PRINCETON CONFERENCE
May 29-31, 1992
Rochester, Michigan

"The 18th Princeton Conference on Cerebrovascular disease will be hosted by the Henry Ford Hospital and Health Sciences Center. The conference will be held at Meadowbrook Hall on the campus of Oakland University, Rochester, MI on May 29-31, 1992. The conference will focus on recent developments in stroke, stroke therapy and future research directions. Conference sessions will include basic and clinical science relevant to the following stroke topics: stroke across age including causes of young stroke, race and sex differences, substance use and abuse, antiphospholipid antibodies, cerebral hemorrhage, brain/heart relationships, applied NMR techniques, therapeutic window including the inflammatory response and the molecular biology of cytoprotection. The conference attendance is by invitation. The organizing committee welcomes communications from prospective participants concerning their work in progress relevant to the above topics. The communications may take any appropriately representative written form, e.g. report, abstract or preprints, but please not after September 30, 1991. The final program will be decided no later than November 5, 1991.

Invitations to participants including travel and lodging will be sent on or before December 1, 1991. All communications should be addressed to Dr. K.M.A. Welch, William T. Gossett Chair, Department of Neurology, Henry Ford Hospital, 2799 W. Grand Blvd., Detroit, MI 48202, Fax: (313) 876-1324."

SAY IT WITH STYLE!

AMA
MANUAL OF STYLE

The one to consult

Whether it's a multi-volume work or a short article, you'll find *the write stuff* in the **AMA Manual of Style.**

This 8th Edition, a major revision, is the *standard* among medical publishers. All major aspects of manuscript preparation are covered in five sections which outline:
- Preparing an article for publication
- Style • Terminology • Measurement and Quantitation • Technical Information and Bibliography.

You'll find everything you need to make your article a success including: • Legal and Ethical Matters • Grammar • Punctuation • Word Use • Foreign Words and Phrases • Diacritics • Abbreviations • Units of Measure • Numbers and Percentages • Mathematics • Statistics • Production and Printing Terms • Editing and Proofreading Marks • Eponyms • Nomenclature • Greek Alphabet • Virus Names • SI Units and Conversion Tables • Expanded Collection of Graphs and Charts • Bibliography • Resources for On-Line Databases.

Next time you have a question about making your medical writing more clear, concise and accurate, be ready with one simple answer — the **AMA Manual of Style.** Order your copy today!

1988/377 pp/4351-X/$26.95

Want it faster? Call FREE 1-800-638-0672 from anywhere in the U.S.

A Comparison of Daily and Alternate-Day Prednisone Therapy in the Treatment of Duchenne Muscular Dystrophy

Gerald M. Fenichel, MD; Jerry R. Mendell, MD; Richard T. Moxley III, MD; Robert C. Griggs, MD; Michael H. Brooke, MD; J. Phillip Miller; Alan Pestronk, MD; Jenny Robison, MS; Wendy King, LPT; Linda Signore, RN, MS; Shree Pandya, MS; Julaine Florence, MS; Janine Schierbecker, PT; Bradley Wilson

• We previously reported the results of a randomized, double-blind 6-month trial of prednisone therapy in which 102 boys aged 5 to 15 years with Duchenne muscular dystrophy received daily doses of 1.5 and 0.75 mg/kg per day and were compared with those receiving placebo. The strength and function in both prednisone-treated groups improved equally and were significantly better than in the placebo group. To compare alternate-day and daily dosing of prednisone with respect to benefits and adverse side effects, the placebo group was started on alternate-day prednisone therapy, and the treatment group regimens were changed to equivalent doses of alternate-day prednisone without breaking the double-blind nature. At the end of 6 months, the group that was changed from daily to alternate-day therapy had declined in strength back to levels observed 12 months previously, at the start of daily therapy. The group in which alternate-day therapy was started showed a significant improvement in strength at 3 months, similar in magnitude to the response of boys treated with daily therapy. However, their strength declined significantly in the subsequent 3 months compared with boys who received daily therapy. The frequency of side effects was not significantly different for alternate-day therapy compared with daily therapy. We conclude that alternate-day prednisone therapy effectively increases strength but does not sustain the improvement to the same extent as daily therapy or mitigate side effects.

(*Arch Neurol.* 1991;48:575-579)

Duchenne muscular dystrophy (DMD), a progressive and fatal disease of skeletal muscle, is a genetic disorder caused by abnormalities at the Xp21 chromosomal site.[1] Affected boys have a complete absence or a reduced or altered size of the structural protein dystrophin in skeletal muscle.[2] The mechanism by which abnormalities of this structural protein produces a clinical syndrome characterized by apparent normal strength at birth and a subsequent progressive muscle deterioration in childhood is not established.[3]

Despite this limited understanding of the pathophysiology, progress has occurred in the development of a treatment. We reported the results of a 6-month randomized, double-blind trial comparing the effects of prednisone (0.75 and 1.5 mg/kg per day) with placebo.[4] Both doses of prednisone significantly improved muscle strength and function compared with placebo. Increased strength was noted as soon as 1 month after the onset of treatment. Strength continued to increase at 3 months and was maintained at 6 months. Both doses of prednisone produced an equivalent response.

In the present study, we sought to compare alternate-day and daily dosing of prednisone with respect to benefits and adverse side effects. Three questions were addressed: (1) Does starting with alternate-day therapy produce the same increase in strength as starting with daily therapy? (2) Can alternate-day prednisone therapy maintain the strength gained after 6 months of daily therapy? (3) Does alternate-day therapy produce fewer adverse side effects than daily therapy?

PATIENTS AND METHODS

A total of 103 boys, aged 5 to 15 years, with DMD were enrolled at the four collaborating institutions for the initial 6-month randomized, double-blind trial of prednisone therapy. Thirty-six were randomized to receive placebo, 33 to receive low-dose prednisone (0.75 mg/kg per day), and 34 to receive high-dose prednisone (1.5 mg/kg per day). Five boys dropped out during the first 6-month study.

Blinding was maintained after the completion of the initial study. In 34 boys who had been receiving placebo, therapy with 2.5 mg/kg of prednisone was started on alternate days. Thirty-one boys were changed from 0.75 mg/kg of prednisone per day to 1.25 mg/kg of prednisone on alternate days, and 33 boys were changed from 1.5 mg/kg per day (maximum, 40 mg) to 2.5 mg/kg of prednisone on alternate days (maximum, 80 mg). Doses were rounded to the nearest 5 mg. Gelatin capsules (No. 3, Eli Lilly & Co, Indianapolis, Ind) containing powdered prednisone were prepared and dispensed from a single pharmacy at The University of Rochester (NY) Medical Center. The capsules included the appropriate milligram-per-kilogram dose plus enough lactose to adjust the final weight to 240 mg. A 6-month supply was dispensed at the onset of the study. One capsule was taken on alternate days at break-

Reprint requests to the Department of Neurology, Vanderbilt University Medical Center, 2100 Pierce Ave, Nashville, TN 37212 (Dr Fenichel).

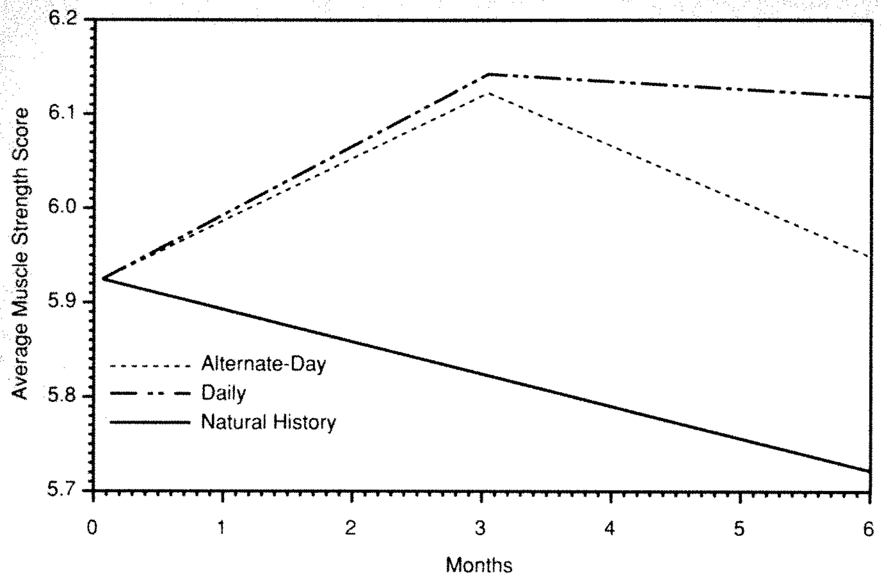

Fig 1.—Graph of least-square means for average muscle strength scores of the group treated with daily prednisone and the group treated with alternate-day prednisone during their initial 6 months of treatment.

fast, and compliance was assessed by weighing the bottles at the time of dispensing and at each return visit.

Two boys dropped out during the present study because of side effects. The number of boys finishing the study were 33 in the group changed from placebo to high-dose alternate-day prednisone, 31 in the low-dose group changed from daily to alternate-day therapy, and 32 in the high-dose group changed from daily to alternate-day therapy.

Clinical Evaluations

All patients were admitted to a Clinical Research Center (CRC) at each collaborating institution at the beginning and at the end of the study. During each CRC admission and on consecutive days, the boys underwent two evaluations of muscle strength, contractures, timed functions, functional grade, lifting of weights, and pulmonary function.[5,6] Clinical evaluations were performed and recorded by Clinical Evaluators who did not inquire about side effects.

Outpatient visits occurred at 1, 2, and 3 months. Clinical evaluations were repeated only at the 3-month outpatient visit. Side effects were evaluated at each outpatient visit and at the CRC admissions by the Principal Investigator without the Clinical Evaluator present. Side effect evaluations included measurement of height, weight, and blood pressure; dip stick measurement of urinary glucose level; and evaluation of behavioral changes, physical stigmas of Cushing's syndrome, cataracts, acne, easy bruising, gastrointestinal symptoms, and hirsutism. Throughout the 12 months of the initial study and the present study, all boys continued to receive calcium carbonate (0.3 g with each meal) and a diet containing 4 g or less of sodium.

Statistical Methods

The relative benefit of starting treatment with alternate-day or daily therapy was made by comparing the measurements made in the placebo group beginning when they changed to alternate-day therapy (second 6 months) with the measurements made when the group treated with 1.5 mg/kg of prednisone first started to receive therapy during the initial study (first 6 months). The mean of measurements at the beginning of the second 6 months was used as the baseline covariate for the placebo group that started to receive alternate-day therapy and those at the beginning of the first 6 months for the prednisone-treated groups. Least-square means were then computed for measurements obtained after 3 and 6 months of therapy. All covariance analyses were computed with Proc GLM of SAS, and type III sums of squares were utilized.[7,8]

The side effects were analyzed with a categorical model with Proc CATMOD in SAS. For the analysis of weight change, a cumulative logit was used as the dependent variable. For the other side effects, the default logit response was used, and paired *t* tests were used to analyze change over time.

The following methods were used to compare the effects of changing from daily therapy to alternate-day therapy. During the CRC admission at the beginning of the study, baseline values were obtained by computing means for each individual measure. Statistical comparisons between high- and low-dose treatment groups at 6, 9, and 12 months were evaluated with use of an analysis of covariance, with each treatment group as the classification variable and the corresponding baseline value for that measure as a covariate. Based on our previous natural history experience, natural log transforms of certain values were utilized when necessary to control for heteroscedasticity. Average muscle strength was chosen a priori as the primary efficacy measure. Least-square means, which adjust the treatment group means for differences in baseline values, were computed for all analyses comparing high- and low-dose prednisone.

Table 1.—Comparison of Daily vs Alternate-Day Prednisone Therapy After 3 Months*

	Least-Square Means		
Measure	Alternate-Day	Daily	*P*
Average muscle strength score	6.14 (0.062) [34]	6.15 (0.069) [30]	.86
Weight lifted, kg	1.49 (0.099) [26]	1.85 (0.094) [29]	.012
Leg function	3.88 (0.119) [33]	3.48 (0.139) [33]	.0497
Time to go 30 ft, s/log (go 30 ft)	8.50/2.14 (0.068) [23]	7.85/2.06 (0.060) [30]	.42
Time to stand, s/log (stand)	5.05/1.62 (0.056) [15]	4.31/1.46 (0.054) [16]	.055
Time to climb stairs, s/log (climb)	4.95/1.60 (0.071) [16]	4.48/1.50 (0.057) [24]	.29
FVC, L	1.60 (0.032) [34]	1.67 (0.035) [28]	.13
MVV, L	41.30 (1.35) [32]	43.90 (1.47) [27]	.21
Systolic BP, mm Hg	106.05 (1.86) [29]	108.15 (1.80) [31]	.42
Diastolic BP, mm Hg	69.40 (1.50) [29]	71.53 (1.45) [31]	.31

*FVC indicates forced vital capacity; MVV, maximum voluntary ventilation; and BP, blood pressure. Values in parentheses are SEs and values in brackets are numbers of subjects.

Paired *t* tests were used to analyze change from the original baseline and from the beginning to the end of the alternate-day therapy period. Single-group *t* tests were used to compare changes in strength scores against natural history trends.[9]

Analyses were performed to compare the side effects experienced by the combined low- and high-dose groups at the 3- and 6-month visits (daily therapy) with the 9- and 12-month visits. For all side effects except weight gain, these matched records were analyzed for change with use of McNemar's test for homogeneity of proportions for correlated samples. For weight gain, a paired *t* test was used to compare the average weight gain for the first 6 months with the average weight gain for the second 6 months. All calculations were performed with SAS.

RESULTS

Starting Therapy: Alternate-Day vs Daily

To compare the 6-month results of starting on alternate-day therapy with those of starting on daily therapy, the average muscle strength scores presented in Fig 1 have been adjusted to the same starting point (the daily treat-

Table 2.—Comparison of Daily vs Alternate-Day Prednisone Therapy After 6 Months*

Measure	Least-Square Means Alternate-Day	Daily	*P*
Average muscle strength score	5.96 (0.052) [34]	6.13 (0.055) [30]	.031

**P* = .21. Values are number (percent).

ment group was started 6 months before the alternate-day therapy group). The average muscle strength scores of boys treated with daily and with alternate-day therapy were substantially stronger after 3 months, and there was no significant difference between the two dosing schedules at 3 months ($P = .86$). However, boys treated daily were significantly better than those treated on alternate days in lifting kilogram weights ($P = .012$) (Table 1).

After 6 months, significant differences were noted between alternate-day and daily therapy (Table 2). Muscle strength, as tested by the average muscle strength score and by amount of weight lifted, was maintained on daily therapy but not on alternate-day therapy. After 6 months of alternate-day therapy, the average muscle strength of the group had declined to the level at the start of therapy (Fig 1). However, because there was no net loss of strength during the 6-month trial, they were still substantially stronger than expected from the natural history data.[6] Contracture index, time to go 30 ft, pulmonary function test results, blood pressure, log creatine kinase level, and creatinine excretion did not differ significantly between daily and alternate-day therapy groups (Table 2).

Six months of treatment with either daily or alternate-day prednisone substantially increased the urinary excretion of creatinine. No significant difference was seen between the two treatment groups ($P = .85$).

The number of boys reporting side effects (Table 3) and the percentage of weight gain (Table 4) were not found to be significantly different in a comparison of 6 months of alternate-day therapy with 6 months of daily therapy.

Changing From Daily to Alternate-Day Therapy

The measurements of efficacy and side effects in the daily low-dose and high-dose (0.75 and 1.5 mg/kg per day) groups and in the alternate-day low-dose and high-dose (1.25 and 2.5 mg/kg per day) groups were not significantly different and have been pooled for clarity of presentation.

Alternate-day prednisone therapy did not further improve or even maintain the increased strength achieved with daily prednisone therapy (Fig 2). At the end of 12 months, the average muscle strength scores were almost the same as they had been before daily therapy was started. The average change during the 12-month period of study was −0.01 units. This, however, was significantly better than the natural history trend of −0.38 units per year that we have reported previously ($P = .0001$).[6]

The time required to go 30 ft, to stand up from a lying position, and to climb

stairs had improved in response to daily therapy but worsened at the end of 6 months of alternate-day therapy, declining toward values observed before daily therapy was initiated. In contrast, the increased level of pulmonary function and urinary creatinine excretion and the decreased level of serum creatine kinase achieved during daily therapy were maintained with alternate-day therapy despite the loss of strength (Table 5).

The proportion of boys exhibiting the typical cushingoid appearance continued to increase from 40% after 6 months to 54% after 12 months. Three boys complained of easy bruising, and two boys developed cataracts during the second 6-month period when they were receiving alternate-day therapy (Table 6). Complaints about gastrointestinal symptoms and behavioral problems decreased. The increase in blood pressure observed during the first 6 months was maintained (Table 5), although the weight gain during the second 6 months was significantly less than that observed during the first 6 months ($P = .0001$) (Table 7).

COMMENT

The present investigation is an extension of our previous 6-month randomized trial that demonstrated a beneficial effect of daily prednisone therapy in boys with DMD.[4] In that study, prednisone both at 0.75 mg/kg per day and at 1.5 mg/kg per day had essentially the same beneficial effects on improving average muscle strength. Further study was indicated to establish whether long-term prednisone therapy could slow the progression of weakness. Before starting long-term therapy, it was important to learn whether alternate-day therapy could provide the same benefits with fewer side effects. Previous studies of other diseases have indicated that alternate-day prednisone treatment is associated with fewer serious side effects than daily treatment while maintaining the desired beneficial effects.[10-12]

Starting Therapy: Alternate-Day vs Daily

Therefore, at the end of the initial double-blind study, we initiated therapy with 2.5 mg/kg on alternate days in the placebo group to compare these boys with the boys who had just completed 6 months of daily prednisone therapy (1.5 mg/kg). To make this comparison, the analyses were statistically adjusted to account for the fact that the patients in whom alternate-day therapy was administered had initially been receiving placebo during the 6-month interval when daily therapy was initiated in the other group. At the time of initial randomization, baseline measurements of strength and function were similar for both groups.[4] However, at the start of the second 6-month study, the average muscle strength scores of the boys already treated for 6 months with daily prednisone were significantly greater than the average muscle strength scores of the boys who had been treated with daily placebo ($P = .0001$). The average muscle strength score of the placebo-treated boys had declined 0.21 ± 0.31 units, as expected from the natural history data.[6]

Therefore, the boys in whom alternate-day prednisone therapy was started were not only weaker than the boys in whom daily prednisone therapy was initiated but they had also been asked about side effects for 6 months before starting prednisone therapy. Despite these limitations in the study design, we believe that the reported analyses of efficacy and side effects of initiating treatment with alternate-day and daily prednisone are informative.

Alternate-day therapy (2.5 mg/kg) led to improvements in muscle strength and function after 3 months that were comparable with the improvements observed in boys receiving daily therapy (1.5 mg/kg). However, the improvements were not maintained at 6 months. Urinary creatinine excretion increased with both alternate-day and daily therapies. These observations suggest that the increase in muscle mass inferred from the rise in creatinine excretion[13,14] does not necessarily correlate with the changes in strength observed in the different groups of patients.

Switching From Daily to Alternate-Day Therapy

In boys who had already experienced a benefit from 6 months of daily prednisone therapy, the regimen was changed to an equivalent dose on alternate days to determine whether the beneficial effects could be maintained while minimizing side effects. Alternate-day doses were selected that approximated the daily dose. Disappointingly, the gains in strength observed after 6 months of daily prednisone therapy were lost during the second 6 months of alternate-day therapy. At the time, we were uncertain whether the loss of benefit was due to the change in dosing or whether it would have occurred with continued daily doses. However, subsequent studies have indicated that daily prednisone therapy has a beneficial effect for 2 years and longer.[15]

Adverse side effects are an important concern when treating children with long-term corticosteroids. The increased reports of cushingoid appearance and cataract during the second 6 months of therapy compared with the first 6 months is probably caused by the total duration of prednisone therapy and not the change from daily to alternate-day therapy. The reduced incidence of gastrointestinal and behavioral symptoms may reflect an increased tolerance for these side effects. Weight gain was reduced when alternate-day therapy was used, but it is likely that the percentage weight gain may be greater during the first 6 months of therapy than the second 6 months without regard to the dosing schedule.

Mechanism of Action

The mechanism by which prednisone produces an increase in strength, function, and muscle mass in boys with DMD has not been addressed herein but has been studied. Muscle biopsy specimens obtained at the conclusion of the first 6 months of treatment in a subset of patients compared placebo with prednisone treatment. Dystrophin analysis failed to reveal any differences between the groups.[16] However, mononuclear cell analysis showed that the prednisone-treated groups had significantly fewer total T cells, cytotoxic/suppressor ($CD8^+$) T cells, and muscle fibers focally invaded by inflammatory cells compared with biopsy specimens from the placebo group.[17] These findings are consistent with the prednisone-induced increase in urinary creatinine excretion, which may represent an increase in muscle mass related to decreased muscle destruction.

This investigation was supported by a grant from the Muscular Dystrophy Association and grants RR00095 (Vanderbilt University, Nashville, Tenn), RR00034 (The Ohio State University College of Medicine, Columbus), RR00044 (University of Rochester [NY]), and RR00036 (Washington University, St Louis, Mo) from the National Institutes of Health, Bethesda, Md.

Vegetative State After Closed-Head Injury

A Traumatic Coma Data Bank Report

Harvey S. Levin, PhD; Christy Saydjari; Howard M. Eisenberg, MD; Mary Foulkes, PhD; Lawrence F. Marshall, MD;
Ronald M. Ruff, PhD; John A. Jane, MD; Anthony Marmarou, PhD

• To elucidate the clinical course of the vegetative state after severe closed-head injury, the Traumatic Coma Data Bank was analyzed for outcome at the time of discharge from the hospital and after follow-up intervals ranging up to 3 years after injury. Of 650 patients with closed-head injury available for analysis, 93 (14%) were discharged in a vegetative state. In comparison with conscious survivors, patients in a vegetative state sustained more severe closed-head injury as reflected by the Glasgow Coma Scale scores and pupillary findings and more frequently had diffuse injury complicated by swelling or shift in midline structures. Of 84 patients in a vegetative state who provided follow-up data, 41% became conscious by 6 months, 52% regained consciousness by 1 year, and 58% recovered consciousness within the 3-year follow-up interval. A logistic regression failed to identify predictors of recovery from the vegetative state.

(*Arch Neurol.* 1991;48:580-585)

The essential feature of the persistent vegetative state (PVS) was characterized by Jennett and Plum[1] as "the absence of any adaptive response to the external environment . . . "(p736). Accordingly, posttraumatic PVS patients are distinguished from other survivors of severe head injury who are capable of making a "consistently understandable response to those around them" either by word or by gesture.[1] Despite the inability to obey commands and no comprehensible speech, patients who survive head injury in a vegetative state (VS) may exhibit eye opening and pursuit eye movements. Few recent studies have focused on the PVS, particularly in relation to head injury. Of 110 PVS patients studied by Higashi and coworkers,[2,3] only 38 had sustained a head injury. These investigators reported a 1 year mortality of 41% overall (26% among the head injured), which increased to 73% over 5 years. Although 10% of these PVS patients partially recovered, only three became communicative.

Jennett and Plum[1] did not specify the minimum duration for posttraumatic VS to be considered persistent. However, serial observations have shown that severely head-injured patients rarely are capable of comprehending simple commands within 1 year if they have not done so by 6 months.[4] Of the patients who eventually obeyed commands by 1 year, Bricolo and coworkers[4] found that 13% had done so after the third month, whereas only 1.5% of the patients began to follow commands after 6 months. Limitations of Bricolo and coworkers' study include the retrospective selection of patients and lack of computed tomographic scan information. In a retrospective study of 134 closed-head injured patients who were in a coma persisting over 30 days, Sazbon and Groswasser[5] found that 72 patients subsequently recovered consciousness (54%), most of them during the second and third month. Of the patients who did not recover consciousness during the study period, approximately two thirds died within the first year. Analysis of acute findings revealed that signs of hypothalamic damage (eg, generalized sweating) and a flaccid motor response most clearly differentiated the recovered from the nonrecovered patients, while epilepsy and hydrocephalus were the late complications that most clearly discriminated the two groups.

Analysis of the International Coma Data Bank of 1373 patients with severe head injury has revealed that 140 were vegetative 1 month after trauma (10%).[6] Fifty-nine of the vegetative patients (42%) regained consciousness within 1 year after the onset of coma, including 14 patients (all younger than 40 years) who became independent. Braakman et al[6] reported that age, pupillary reactivity to light, and the best motor response were the most useful prognostic factors for death or continued VS at various time points. Despite wide variation across the four International Coma Data Bank centers in the percentage of patients who were vegetative at 1 month, the findings uniformly ranged from 1% to 2% by 1 year.

This study was undertaken to (1) evaluate the percentage of severely head-injured patients remaining vegetative at the time of hospital discharge following state of the art neurosurgical treatment at four university trauma centers in the United States; (2) characterize the clinical features of patients

discharged in a VS compared with conscious survivors and patients who die while hospitalized; (3) assess the likelihood of recovery from a vegetative condition over the first 3 years after injury; and (4) identify prognostic factors for vegetative patients regaining consciousness.

PATIENTS, MATERIALS, AND METHODS

Patients

Entry criteria for the Traumatic Coma Data Bank[7] (TCDB) included a severe head injury followed within 48 hours by evaluation of the patient in the emergency department at one of the four participating centers (Table 1) as being in a comatose condition as defined by the postresuscitation Glasgow Coma Scale (GCS) of Teasdale and Jennett[8] indicating a score of 8 or less corresponding to no eye opening, inability to obey commands, and absence of comprehensible speech. Patients exhibiting delayed deterioration also were entered into the TCDB, provided that coma ensued within 48 hours of injury. In contrast to the International Coma Databank, there was no stipulation of a 6-hour duration of coma as an eligibility criterion in the TCDB. Of 1030 patients entered into the TCDB, 167 (16.2%) were excluded from this analysis because they sustained gunshot wounds, 121 (14.2%) were deleted because they were brain dead on admission, and 92 (12.4%) were excluded because they were younger than 16 years, leaving 650 patients available for analysis.

Procedures and Schedule of Follow up

The Glasgow Outcome Scale of Jennett and Bond[9] was completed by a neurosurgeon on discharge from the TCDB hospital and at the time of the follow-up examinations that were scheduled at approximately 6 months, 12 months, 2 years, and 3 years after injury. Assessment using the Glasgow Outcome Scale was based on a neurologic examination, interview with the patient, and/or information obtained from the family. The Glasgow Outcome Scale was completed on the basis of a telephone interview with a family member for patients who were unable to return for follow-up. Evaluation of the capacity of patients to execute simple commands (the essential distinction between nonvegetative and vegetative survivors) has been shown to be highly reliable across different clinical examiners.[10]

Analytic Methods

The data were analyzed using χ^2 tests of association, tests for trend, nonparametric methods for comparisons of groups in the absence of normality, survival analyses, and logistic regression.

RESULTS

VS at Discharge

To focus on the comparison between vegetative and conscious survival, the data of patients classified as moderately disabled, severely disabled, or as having made a good recovery were merged into a single category referred to as "nonvegetative." Patients who died were included in the analysis to determine whether their demographic and clinical features more closely resembled the findings in cases of VS as opposed to conscious survivors. This issue is particularly germane to previous studies that have combined the data of patients who died with those who remained vegetative for comparison with conscious survivors.[11,12] Additional analyses were confined to those patients who were vegetative at discharge, and some analyses further excluded those patients who died without recovering from the VS.

Figure 1 shows the distribution of discharge status for each of the four TCDB centers. Overall, 93 of the patients (14%) were discharged from the hospital in a VS. It is seen that the likelihood of this outcome was fairly constant across the four university hospitals. In view of the similar distribution of vegetative survivors across the four TCDB centers and no significant center differences in the distribution of Glasgow Outcome Scale categories at (1) 6 months; (2) 1 year; (3) 2 years; and (4) 3 years; all additional analyses are reported for the total cohort eligible for analysis. Although the initial assessment of outcome was at discharge instead of the 1-month interval employed by Braakman et al,[6] the median length of stay approximated 1 month and three fourths of the patients spent less than 2 months in a TCDB hospital.

Tables 1 through 4 compare the demographic and clinical findings of the 93 patients who were vegetative at the time of discharge from a TCDB center with the corresponding data of nonvegetative survivors and patients who had died. As shown in Table 1, both groups of survivors were significantly younger

Table 4.—Complications of Injury in Relation to Outcome at Discharge (No. of Patients With Complication/No. of Patients With and Without Complication)*

	No. (%)					
	Nonvegetative	**Vegetative**	**Dead**	**Total**	χ^2	***P***
Shock	66/291 (23)	35/80 (44)	89/189 (48)	**190/560** (34)	36.32	<.0001
Hypoxia	58/189 (31)	18/41 (44)	49/105 (47)	**125/335** (37)	8.24	<.016

*Shock was defined by a drop in systolic blood pressure of less than 90 mm Hg. Hypoxia was defined by a Po_2 of less than 60. These values were recorded in the emergency department at the time of hospital admission. There was variation in the sample size of each group available for analysis because only patients with complications coded as unequivocally present or absent were included.

than the patients who died, whereas the age of vegetative patients did not significantly differ from patients whose consciousness had improved by discharge. Vegetative patients were hospitalized for longer durations at a TCDB center than were conscious survivors (Table 1). It is conceivable that the long duration of hospitalization in the VS patients reflects unavailability of suitable rehabilitation for this group.

Patients who were vegetative at discharge sustained more severe injuries than the conscious survivors, as reflected by their lower postresuscitation GCS scores and more frequent abnormal pupillary reactivity (Table 2). The distribution of GCS scores in the vegetative survivors is similar to the findings obtained in patients who died. However, bilateral pupillary abnormality was more common in fatal injuries compared with the group with vegetative survival, $\chi^2(1)=56.3$, $P<.0001$.

Intracranial diagnosis was characterized using a classification based on the initial computed tomographic scan.[7] In addition, a separate category was designated for patients with brain-stem lesions. In comparison with patients who were following commands at discharge, the intracranial diagnosis of vegetative survivors was distinguished primarily by diffuse injury complicated by swelling or shift of midline structures (Table 3). In contrast, the frequency of mass lesions (total of evacuated and nonevacuated) was similar in vegetative (36%) and nonvegetative (40%) patients, but less common than in patients who died (57%), $\chi^2(1)=19.0$, $P<.0001$.

The presence of shock or hypoxia was analyzed in relation to outcome at hospital discharge for those patients in whom either of these complications was unequivocally present or absent (Table 4). The presence of shock, as defined by a drop in systolic blood pressure to below 90 mm Hg, was more common in patients who died or were vegetative at discharge compared with conscious survivors. Although variation in hypoxia (Po_2, <60) across the groups was less impressive than the disparities in shock, patients who regained relatively normal consciousness by the time of discharge tended to have more normal oxygenation of brain tissue than vegetative survivors or patients who died (Table 4). Intracranial pressure was analyzed according to the maximum value and the percent time it exceeded 20 mm Hg during the first 72 hours of the intensive care phase. Table 1 indicates that intracranial hypertension (reflected by maximum intracranial pressure and the percent time intracranial pressure exceeded 20 mm Hg) was more frequent in the patients who died. Although VS patients tended to have elevated intracranial pressure during a greater percentage of the first 72 hours than patients who were conscious by the time of discharge, this difference was not significant.

Recovery From VS

Of 93 vegetative survivors, outcome data were available for 84 (90%) at least 6 months after injury, whereas nine patients (10%) were unavailable for follow-up. The last follow-up assessment was completed at 6 months in 18 patients (21% of series), 1 year in 35 patients (42% of series), 2 years in 25 patients (30% of series), and 3 years in six patients (7% of series). The demographics and clinical features of patients who recovered from a VS were compared with those who either remained vegetative or died. Table 5 indicates that 49 of the patients discharged in the VS (58%

of the cases with follow-up data) exhibited improvement in level of consciousness within 3 years after injury, whereas 35 of the patients (42%) remained vegetative (n = 15) or died (n = 20) during the follow-up period. Death following discharge in a VS was attributed to medical complications (11 patients), the direct effects of head injury (four patients), or other causes (five patients).

Thirty-four of the vegetative patients (40% of patients with follow-up data) who eventually improved to a higher Glasgow Outcome Scale category had done so by 6 months. Figure 2 depicts the cumulative percentage of vegetative patients who became conscious during the follow-up period. By 1 year after injury, 52% of the VS patients with follow-up data had regained consciousness. As shown in Fig 2, increments in the percentage of vegetative patients who recovered consciousness were slight beyond 1 year, with 49 patients (58% of patients with follow-up data) improved by 2 years. In view of the variable duration of follow-up, Fig 2 should be interpreted as a life-table estimate.

To identify features related to recovery from a VS, the statistical analyses were based on a dichotomy of improved patients vs those who remained vegetative or died during the 2 years. As depicted in Table 5, patients who recovered tended to be younger than survivors who remained vegetative or died, but the difference in age was not significant.

Table 6 shows that the preponderance of patients had a postresuscitation GCS score in the 3 to 5 range irrespective of whether they recovered from a VS at discharge. A repeated analysis confined to the motor component of the GCS also revealed no relationship to recovery from VS. Similarly, nonreactive pupils were common in vegetative survivors regardless of later improvement (Table 6).

The relationship between complications of injury and recovery from PVS is summarized for pulmonary problems, shock, and hypoxia in Table 7. Analysis was confined to unequivocal presence or absence of these complications, excluding "suspected" cases. Of the comparisons between patients who regained consciousness vs those patients who remained in a VS, the only significant finding was an association between absence of hypoxia and PVS (Table 7). Paradoxically, the percent of patients with hypoxia who recovered from PVS was higher than in the patients who remained vegetative. A logistic regression was performed to evaluate the usefulness of patient features in predicting outcome

Table 5.—Outcome of Vegetative State Within 3 Years in Relation to Age at Injury and ICP During First 72 Hours*

Nonevacuated mass lesion	1 (6.7)	3 (6.1)	0 (0)

*Classification of intracranial diagnosis followed previously described guidelines.[7] CT indicates computed tomography.

of VS (ie, improved vs PVS/dead). This analysis disclosed that neither age, pupillary reactivity or swelling on computed tomography were sufficiently predictive of outcome to be selected for entry ($P<.01$) in a regression equation. Further analysis disclosed a nonsignificant trend of more frequent complications in the PVS patients compared with patients who regained consciousness. These findings include posttraumatic hydrocephalus (33% in PVS compared with 24% of improved patients), seizures (13% vs 10%), and inappropriate secretion of antidiuretic hormone (7% vs 4%). Diabetes insipidus occurred in 18% of the patients who improved and in no patient who remained vegetative.

Table 8 shows the distribution of intracranial diagnosis based on the initial computed tomographic scan in the PVS patients, patients who improved, and those who died. It is seen that more than 90% of the PVS patients and patients who regained consciousness had abnormal computed tomographic scans. Diffuse injury with brain swelling was the most common intracranial diagnosis in both groups of survivors. The clearest distinctions seen in Table 8 are the greater observed percentage of uncomplicated diffuse injury among patients who regained consciousness as opposed to the more frequent brain swelling complicating diffuse injury among the PVS patients. Patients who died were distinguished primarily by the higher observed percentage of evacuated mass lesions. There was no significant association between intracranial diagnosis and recovery from a VS.

COMMENT

Despite state-of-the-art neurosurgical management of severe closed-head injury, 14% of the TCDB cohort (excluding gunshot wounds and patients who were brain dead on admission) were discharged from a center hospital in a VS. This proportion of vegetative patients, which was comparable across the four TCDB centers, slightly exceeded the 10% rate of VS obtained from the International Coma Data Bank 1 month after severe injury.[6] In this study, patients discharged in a VS had longer hospital stays than conscious survivors, thus ruling out the possibility that early transfer to a rehabilitation hospital contributed to our findings. In contrast to the International Coma Data Bank,[6] the age of vegetative survivors did not differ from patients who were conscious at the time of discharge from a TCDB hospital, although both groups were younger than hospitalized patients who died from their injuries.

Analysis of the clinical features disclosed that the VS group had lower GCS scores and more frequently exhibited nonreactive pupils than conscious survivors. The severity of impaired consciousness and the frequency of pupillary abnormalities among the vegetative survivors approximated the findings in patients who died before discharge. In contrast, the intracranial pressure values did not differentiate the conscious survivors from the patients discharged in a VS. A review of the intracranial diagnosis, based on the computed tomographic scan and surgical findings, disclosed that diffuse injury associated with brain swelling or shift of midline structures tended to most clearly differentiate the VS patients from conscious survivors. However, even this distinction was limited by considerable overlap (Table 8).

Following discharge in a VS, 52% of the TCDB patients with follow-up data recovered consciousness by 1 year and 58% had improved by the 3-year follow-up interval. Notwithstanding the nine patients (10% of our cohort) for whom follow-up data were unavailable, our findings are in close agreement with a recent study by Sazbon and Groswasser[5] who reported that 54% of closed-head–injured patients eventually regained consciousness after a 1-month duration of "prolonged unawareness," which appeared to be functionally equivalent to VS. Although only 42% of the VS patients in the International Coma Data Bank improved within 1 year after injury,[6] the patient characteristics in this cohort differed from the TCDB patients who were discharged in a VS. Our patients tended to be younger than the posttraumatic VS group studied by Braakman et al.[6] Accordingly, age was prognostic of recovery from VS in the International Coma

Data Bank but not in our cohort. In addition, the TCDB deleted the eligibility requirement of 6 hours of coma that had been used in the International Coma Data Bank.

Taken together with previous longitudinal studies of outcome of posttraumatic VS,[4-6] our findings indicate that recovery from a VS is most likely to occur during the first year as only 6% of the patients followed up improved between the first and second years. Although our data do not exclude the possibility of vegetative patients regaining consciousness after the second year, improvement at such a late stage must be regarded as a rare event.[4,6] In this study, analysis of demographic and neurologic features failed to identify any useful prognostic indicators of recovery from VS. The article by Braakman et al[6] stated that recovery from VS could be predicted by the combination of age and pupillary reactivity to light, and the best motor response received no support from our analysis of the TCDB nor were we able to confirm the prognostic features identified by Sazbon and Groswasser.[5] In contrast to the lack of predictors of recovery from VS, analysis of the TCDB disclosed that the lowest postresuscitation GCS score and pupillary reactivity were predictive of neurobehavioral outcome at 1 year after injury in conscious survivors.[13]

Based on the experience of the TCDB, we postulate that a physiologic measure such as the regional cerebral metabolic rate for glucose and cerebral blood flow may be more useful in predicting the outcome of VS. This possibility is supported by a recent study using positron emission tomography in which cerebral metabolism and cerebral blood flow were markedly lower in vegetative vs locked-in patients.[14]

This study was supported by the Traumatic Coma Data Bank (TCDB) under Contracts NO1-NS-3-2339, NO1-NS-3-2340, NO1-NS-3-2341, NO1-NS-3-2342, NO1-NS-6-2305, and grant NS-21889 from the National Institute of Neurological Disorders and Stroke.

The TCDB Manual of Operations that includes the TCDB data forms is available from the National Technical Information Service, US Department of Commerce, 5285 Port Royal Rd, Springfield, VA 22161 (NTIS Accession No. PB87 228060/AS).

We are indebted to Arthur L. Benton, PhD, for his comments and suggestions and to Karen Wilkinson and Liz Zindler for assistance in the manuscript preparation.

The Influence of Gender on the Susceptibility to Multiple Sclerosis in Sibships

Adele D. Sadovnick, PhD; Dennis E. Bulman, MSc; Lara Hashimoto; Marie B. D'Hooghe, MD; George C. Ebers, MD

• A population-based study of pairs of relatives (siblings, second- and third-degree) concordant for multiple sclerosis did not show an excess of like-sexed pairs. In addition, data on human lymphocyte antigen typing for sibling pairs concordant for multiple sclerosis did not find an increase in haplotype sharing for like-sexed pairs. These data do not support the notion that sex-related factors influence multiple-sclerosis susceptibility in families.

(*Arch Neurol.* 1991;48:586-588)

Multiple sclerosis (MS) is one of the most common causes of neurological disability in young adults and is characterized by variable clinical features. In Canada, it has been shown that the prevalence of MS exceeds 1 per 1000 population.[1-3] Although the cause of MS remains unclear, there is increasing evidence that genetic factors play an important, if not essential, role in disease susceptibility.[4,5]

It appears likely that a significant portion of MS susceptibility is polygenic.[6] One susceptibility gene may be linked to histocompatibility antigen (HLA), and others are suspected.[7] Recent evidence suggests that both α and β chains of the T-cell receptor may also be associated with MS, both on a population basis and, for the β chain, in sibling pairs.[8-10] Another susceptibility factor may be sex-related since MS occurs in women approximately twice as often as in men and sex may interact with HLA.[11] In systemic lupus erythematosus where a female-to-male ratio of 10:1 exists, it has been shown that sex and HLA may interact.[12,13]

Weitkamp[14] suggested that the gender of an MS patient may have a modifying role in MS susceptibility by interacting with other factors, such as products of the HLA supergene (the HLA-A3, -B7, -DR2 haplotype is strongly associated with MS[6,15]). Evidence presented by Weitkamp[14] in support of this hypothesis was that relatives (siblings, second- and third-degree) concordant for MS were like-sexed more often than expected by chance.

In the present study, we report observations from two geographically based Canadian MS clinics located in London, Ontario, and Vancouver, British Columbia. The populations of these two regions largely consist of individuals of northern European ancestry, especially from the British Isles. Using data on index cases and their relatives, we attempted to replicate Weitkamp's[14] observations.

PATIENTS, MATERIALS, AND METHODS

The study population consisted of 3046 consecutive, unrelated MS[16] patients attending the clinics in London (N = 1400) and Vancouver (N = 1846). Whenever possible, reportedly affected relatives of patients with index cases were also examined at one of the clinics. If this was impossible, a clinic neurologist reviewed relevant clinical and/or autopsy reports prior to accepting the relative as having MS according to present-day diagnostic criteria.[16]

Data on nine sibships with three siblings having MS and one sibship with five affected siblings were examined separately.

Pairs of relatives were divided into the following three groups: (1) male-male pairs, (2) female-female pairs, and (3) male-female pairs. "Expected" values for the distribution of "like-sexed" or "unlike-sexed" sibling pairs were calculated from the total number of affected male and female subjects in the study population, assuming a random distribution. The data were analyzed for sibling pairs, second-degree relatives (aunt/uncle; niece/nephew; grandparent/grandchild), and first cousins. Parent/child pairs concordant for MS were examined as a separate study population.[17] Data on HLA typing were compiled by combining previously published results.[18,19]

Data on pairs of relatives were analyzed using 2×2 contingency χ^2 analyses. The methodology for HLA typing and the calculation of the expected distribution of haplotype sharing among siblings have been described elsewhere.[18] Differences were considered significant at the 5% ($P<.05$) level.

RESULTS

Sibling Pairs

Comparison of the Distribution of Like-Sexed and Unlike-Sexed Pairs.—A total of 138 concordant sibling pairs (excluding twins and sibships with three or more siblings with MS) were identified from the clinic populations in London (N = 62) and Vancouver (N = 76). There were a total of 83 like-sexed pairs (16 male-male; 67 female-female) and 55 unlike-sexed pairs. The distribution of male-male, female-female, and male-female sibling pairs did not differ significantly between the two clinics ($\chi^2 = 3.95$, df = 2; $P>.05$). Data from both clinics were, therefore, combined for subsequent analyses. As shown in Table 1, the observed number of like-sexed sibling

---

From the Department of Medical Genetics and Multiple Sclerosis Clinic, University Hospital–University of British Columbia Site, University of British Columbia, Vancouver (Dr Sadovnick); and Multiple Sclerosis Clinic, University Hospital, University of Western Ontario, London (Mr Bulman, Ms Hashimoto, and Drs D'Hooghe and Ebers).

Reprint requests to Department of Medical Genetics, University of British Columbia, 226-6174 University Blvd, Vancouver, British Columbia, Canada V6T 1Z3 (Dr Sadovnick).

pairs was not significantly different than expected ($\chi^2=0.62$, df=1; $P>.05$).

Among the siblings concordant for MS, there were 189 female and 87 male subjects with a female-to-male ratio of 2.1:1. This ratio is similar to the 2:1 ratio observed in the clinic populations.[17]

As seen in Table 1, the nine sibships with three siblings concordant for MS consisted of 14 female and 13 male subjects with a female-to-male ratio of 1.1:1. In one family, there were five siblings with MS (three were female and two were male) with a female-to-male ratio of 1.5:1.

HLA Typing.—Data on HLA typing were available for 48 concordant sibling pairs for whom unequivocal haplotypes were derived[18,19] from the London clinic. As shown in Table 2, the data did not differ from the expected distribution for female-female pairs ($\chi^2=2.43$, df=2; $P>.05$), male-male pairs ($\chi^2=0.33$, df=2; $P>.05$), or female-male pairs ($\chi^2=2.05$, df=2; $P>.05$).

Second-Degree Relative Pairs

From the Vancouver clinic, data were available for 70 pairs of second-degree relatives concordant for MS. As shown in Table 3, the observed number of like-sexed sibling pairs was not significantly different from expected ($\chi^2=0.009$, df=1; $P>.05$). The female-to-male ratio for second-degree relatives concordant for MS was 1.9:1 (92 female and 48 male subjects), not significantly different from the 2:1 ratio for the clinics.[17]

First-Cousin Pairs

From the Vancouver clinic, data were available for 64 pairs of first cousins concordant for MS. As shown in Table 3, the observed number of like-sexed sibling pairs was not significantly different from expected ($\chi^2=2.59$, df=1; $P>.05$). The female-to-male ratio for first cousins concordant for MS was 2.0:1 (85 female and 43 male subjects), not significantly different from the 2:1 ratio for the clinics.[17]

COMMENT

It has been proposed by Weitkamp[14] that gender is a risk factor for MS susceptibility, either independent of or interactive with other disease susceptibility genes. If sex is related to disease susceptibility, affected relatives would be more likely to have susceptibility genes identical by descent and the interaction between these genes and sex may be hypothesized to result in a higher proportion of like-sexed concordant relatives than predicted, based on the frequency of male and female subjects in the study population. Weitkamp[14] supported this view by showing that concordant pairs of relatives were more often like-sexed. However, his study is open to criticism as ascertainment was suboptimal and consisted of a literature review for the years 1896 through 1981 inclusive. Publication itself introduces selection biases,[4,20] and the hazards of this type of ascertainment were recognized by Weitkamp. As our study group was identified from two large, population-based MS clinics, ascertainment biases with regard to the sex of affected relatives are minimal. In addition, in the present study, all patients and their relatives were thoroughly assessed and assigned a diagnosis according to standard, recognized criteria,[16] impossible in a literature review. Finally, an excess of concordant, like-sexed sibling pairs does not necessarily imply a genetic mechanism since such pairs may, in fact, have more environmental sharing compared with unlike-sexed siblings.[20] However, it must be noted that unlike-sexed siblings of MS patients still have a significantly greater risk to develop the disease compared with the general population,[5] thus providing more evidence for a possible interaction between genetic susceptibility and environmental sharing.[21,22] Although the data are derived from multiplex sibships, the findings may be equally applicable to both familial and nonfamilial MS, since no differences have yet been found between familial and sporadic cases.[23]

Data from the present study do not support the finding of Weitkamp.[14] An excess of like-sexed pairs was not observed among siblings, second-degree relatives, and first cousins concordant for MS. Our data on parent-child pairs, identified from the same clinic populations and presented elsewhere,[17] are in agreement with those of Weitkamp in that they do not show an excess of like-sexed pairs. In fact, our data show a definite paucity of father-son pairs, whereas the number of mother-daughter, father-daughter, and mother-son pairs occur as expected, based on the female-to-male ratio among MS patients.

Weitkamp[14] also reported an increase in HLA haplotype sharing in female-female sibling pairs concordant for MS. The data on HLA typing presented in this article, an extension of an earlier report,[18] do not substantiate Weitkamp's observations. It is, however, of interest that in lupus erythematosus, a disease with a high preponderance of female patients, male patients show a significant increase in the frequency of HLA-B8 compared with control subjects,[12,13] suggesting that the susceptibility threshold in the relatively resistant male subject is raised by the presence of HLA-B8 DR3. In MS, a sex-related HLA association has been reported (data from London), with female patients having a significantly higher frequency of DR2 compared with male patients and female control subjects.[24]

In general, there is a female sex preponderance among MS patients. In contrast to the data presented by Weitkamp,[14] ours do not indicate a difference in the female-to-male ratio between the general clinic populations and sibships with two affected members, second-degree relatives, or first cousins concordant for MS. Although the numbers are small, a decreased female-to-male ratio (1.1:1) was observed in the nine sibships with three affected members, but the one family with five affected siblings consisted of three female and two male members with a female-to-male ratio of 1.5:1. The influence of the female sex on MS susceptibility may have a parallel in experimental allergic encephalomyelitis, of which the clinical manifestations are limited to juvenile female subjects in the resistant strain-2 guinea pigs.[25] This finding is consistent with the effect of sex on immune responsiveness in this increasingly relevant animal model.

Grufferman and coworkers[22] reviewed the literature on Behçet's disease, Hodgkin's disease, and sarcoidosis and found evidence for increased sex concordance among affected sibling pairs. These data were compared with the findings of Weitkamp.[14] The paucity of concordant conjugal pairs compared with concordant sibling pairs for these four diseases suggests that if shared environmental exposures play a role in family aggregations, these would have to occur during childhood or adolescence.[22] It is possible that gender influences susceptibility on more than one level, as is seen in several animal models of spontaneous autoimmune disease.[26]

In summary, our data do not provide evidence for a relationship between sex and disease susceptibility in relatives concordant for MS.

This study was supported by a grant from the Multiple Sclerosis Society of Canada. Mr Bulman and Ms Hashimoto received personal support from the Multiple Sclerosis Society of Canada, and Dr Sadovnick received partial personal support by a grant from the Multiple Sclerosis Society of Canada, British Columbia Division.

The assistance of I. Yee with the data analyses is greatly appreciated. The authors would like to thank S. A. Hashimoto, MD, J. Hooge, MD, L. Kastrukoff, MD, J. Noseworthy, MD, J. J-F. Oger, MD, G. Rice, MD, and B. Weinshenker, MD, for their assistance with interpreting neurological data on multiple sclerosis clinic patients and their relatives.

Incidence and Prevalence of Amyotrophic Lateral Sclerosis in Harris County, Texas, 1985-1988

John F. Annegers, PhD; Stanley Appel, MD; Ju Ruey-Jiuan Lee, MPH; Penny Perkins, MPH

• The incidence of amyotrophic lateral sclerosis was determined in Harris County, Texas, for the period 1985 through 1988. Amyotrophic lateral sclerosis cases were ascertained from four sources: area neurologists, hospitals, death certificates, and the Muscular Dystrophy Association. The age-adjusted incidences of 1.27 per 100 000 person-years in males and 1.03 per 100 000 person-years in females were lower than recent rates in the northern US, Canadian, and northern European studies but higher than rates in southern European studies. Comparisons with other recent incidence studies show less uniformity in occurrence of amyotrophic lateral sclerosis, in both the overall rates and in the age- and sex-specific patterns, than was suggested by mortality studies. The incidence of amyotrophic lateral sclerosis among blacks and whites was similar. Hispanic males had incidences similar to white males, although a deficit of female Hispanic cases was found in Harris County. The prevalence of amyotrophic lateral sclerosis peaked in the 65- to 74-year age group at 33 per 100 000 population among males and 19 per 100 000 population for females.

(*Arch Neurol.* 1991;48:589-593)

Amyotrophic lateral sclerosis (ALS) is a progressive disorder of the nervous system that causes degeneration in both upper and lower motor neurons and is characterized by muscular weakness with atrophy, fasciculations, and labioglossopharyngeal paralysis. Amyotrophic lateral sclerosis is uncommon under the age of 40 years, and the incidence progressively increases to at least the age of 70 years, beyond which age most studies show a leveling off or a declining incidence. The clinical course results in death within 5 years from onset in over 80% of cases. For some time, worldwide mortality rates of ALS have shown a strikingly uniform pattern with the exceptions of several foci of extremely high endemicity in the western Pacific. More recent mortality and incidence studies have tended to demonstrate greater population variations and a possible secular increase in occurrence. A trend of increasing ALS death rates has been reported from France,[2] Finland,[3] Scotland,[4] and the United States[5] over the past generation. Morbidity studies in Nova Scotia,[6] Minnesota, Scotland,[4] and Israel[8] have also suggested a secular increase in incidences. However, it is not known to what extent that increase is real or an artifact of more complete case ascertainment.

The purpose of this study was to determine the incidence and prevalence of ALS in Harris County, Texas, for the period 1985 through 1988, and to compare these findings with other populations. This population differs from other populations where the incidence of ALS has been determined in several major ways. Harris County, which includes the city of Houston, is a large urban center with an estimated average population (1985 through 1988) of 2 937 875. The city is multiethnic, with 62% of the total population northern European white, 19% black, and 19% Hispanic. Harris County has been at the heart of the United States petrochemical industry over the last 50 years. Harris County, located on the Gulf Coast, has a subtropical climate, which allows latitudinal comparisons with previous studies.

SUBJECTS AND METHODS

The study population consisted of Harris County residents during the period 1985 through 1988. Cases were ascertained from four sources: (1) Harris County hospitals; (2) neurologists practicing in Harris County and adjacent Galveston County, Texas; (3) the Muscular Dystrophy Association; and (4) death certificates from the Texas Department of Health. Letters were sent to the 149 neurologists who were listed with the Texas Board of Medical Examiners (May 1988) and the 65 hospitals, listed with the Greater Houston Hospital Council, that serve the adult population in the county.

Each hospital contact was asked to generate a computer list of discharges during the study period with the *International Classification of Diseases, Ninth Revision, Clinical Modification* (*ICDA-9-CM*) code 335.2. If this was not possible, monthly microfilm and computerized disease indexes were reviewed to obtain the names of patients discharged with the disease code of interest. Of the 65 hospitals contacted, 61 participated. Three of the four nonparticipating hospitals did not have adequate computer capabilities to obtain names by discharge diagnosis, and the other ceased operation in 1988. The nonparticipating hospitals listed the numbers of operational beds as 50, 114, 191, and 320.

Of the 149 Harris and Galveston County neurologists, 101 participated in the study, 32 refused, and 16 had moved out of state or could not be located. Participation was defined as either supplying us with names of cases, stating that no cases of ALS had been seen during the study period, or stating that all cases of ALS were referred to a participating neurologist. Two participating neurologists who specialize in ALS provided extensive computer lists of the patients seen during the study period. Almost half of the nonparticipating neurologists (15 of the 32) practiced in Galveston County. One of these

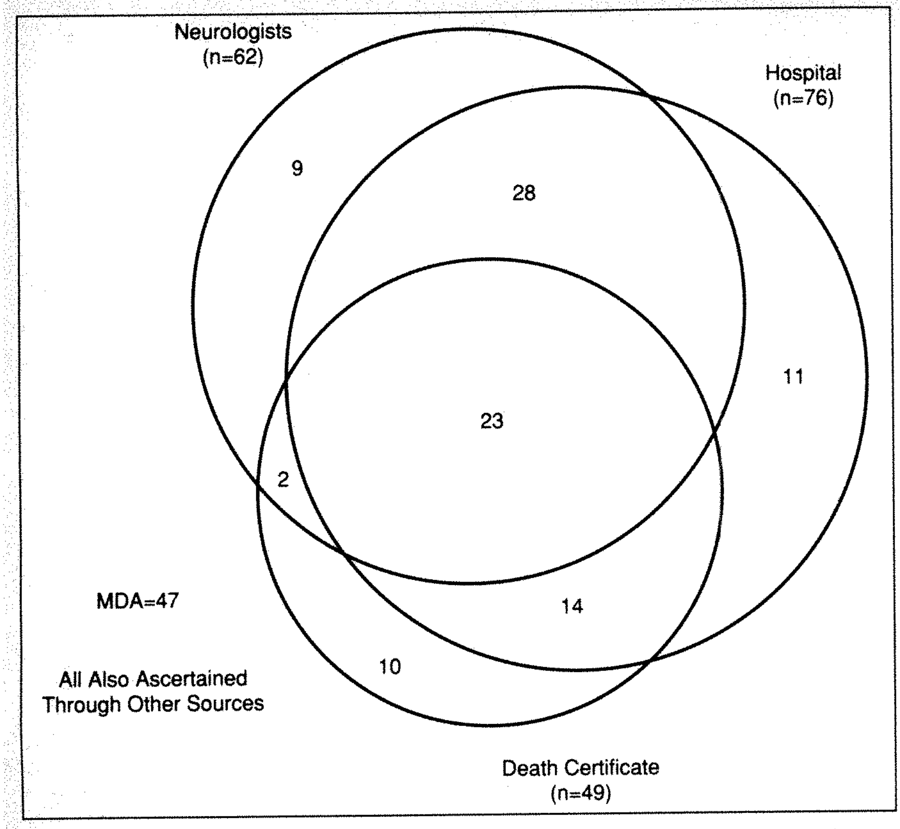

Fig 1.—Amyotrophic lateral sclerosis sources of independent case ascertainment, Harris County, Texas, 1985 through 1988. MDA indicates Muscular Dystrophy Association.

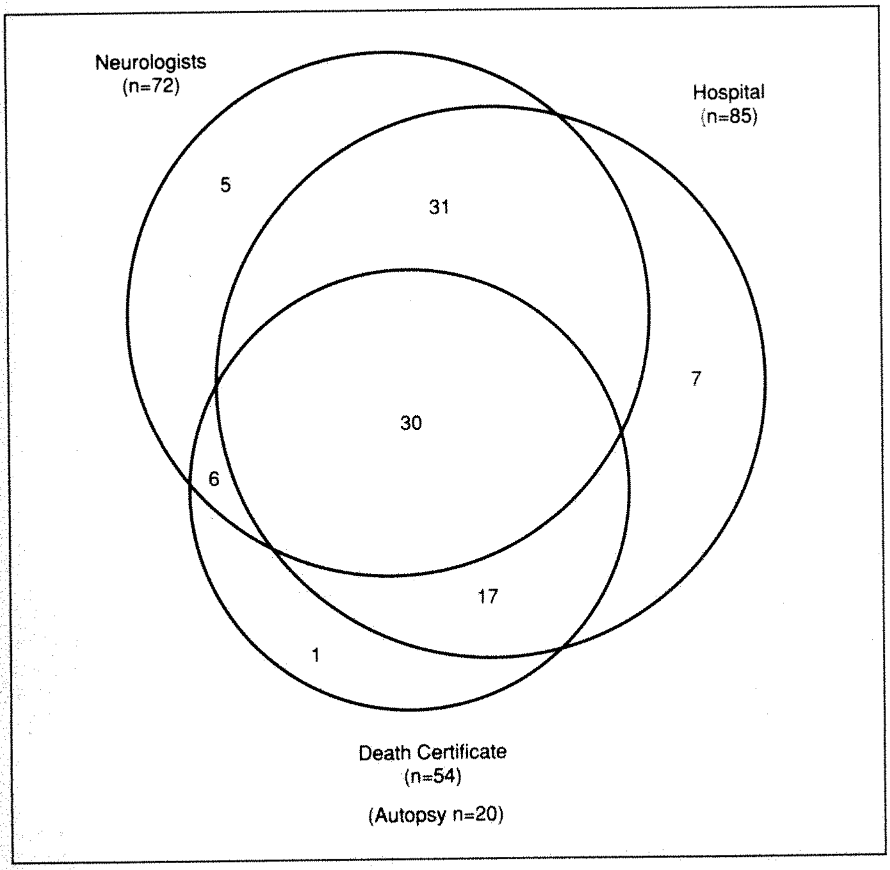
Fig 2.—Amyotrophic lateral sclerosis sources of diagnostic information on 97 incidence cases, Harris County, Texas, 1985 through 1988.



neurologists stated that, to his knowledge, all patients from Harris County with ALS would also have been seen by neurologists in Harris County.

The Muscular Dystrophy Association disseminates information about ALS and assists patients with diagnosis and follow-up care at Muscular Dystrophy Association clinics. Muscular Dystrophy Association records were reviewed for patients with ALS who applied for assistance or were on the current or inactive mailing lists. Patient files were reviewed for the names of the attending neurologists. The neurologists were then contacted for additional information on the case to complete the abstract form and substantiate the diagnosis. Death certificates were obtained from the Texas Department of Health for deaths between January 1985 and December 1989. Search specifications were for certificates with causes of death due to ALS (*ICD-9-CM* 335.2).

Criteria for qualification as an incident case were an initial diagnosis of ALS among Harris County residents between 1985 and 1988. Prevalent cases were of those patients alive and residing in Harris County on January 1, 1989. Addresses were checked with the Houston and Harris County Atlas as well as the Polk Directory and the Southwestern Bell telephone directories when necessary. Clinical information was abstracted from the medical records. Physician diagnosis of ALS was substantiated by patient history and physical examination, electromyogram results, muscle biopsy specimen analysis, death certificate, and autopsy findings. Patients with clinical findings more consistent with other motor neuron diseases, eg, primary lateral sclerosis, progressive muscular atrophy, or polyneuropathy, were excluded. If the diagnosis was uncertain owing to an atypical clinical presentation, coexisting medical conditions, or conflicting diagnoses of two or more neurologists, the completed abstract forms were reviewed by the study neurologist (S.A.) for final determination of case status. Harris County population estimates for each year from 1985 through 1988 were obtained from projections by the Texas Department of Health. The estimates were provided by age, sex, and ethnicity. Age-adjusted rates and age- and sex-adjusted rates were calculated using the 1970 US population as the standard. Ninety-five percent confidence intervals (CIs) were calculated assuming a Poisson distribution.[9] The cumulative risks for Harris County and other populations were computed from the age-specific rates to the age of 80 years using the density method.[10]

RESULTS

A total of 97 incident cases of ALS diagnosed from 1985 through 1988 were identified. Of these, 62 were independently ascertained from neurologists, 76 from hospitals, and 49 through death certificates (Fig 1). The proportion from death certificates was lower than the 80% of patients with ALS who die of ALS because some of the incidence patients were still alive. All 47 of the incidence cases ascertained from the Muscular Dystrophy Association (not shown in Fig 1) were also independently ascertained from at least one other source. Ten cases were independently ascertained solely through death certificates, 11 solely from hospital admissions, and nine solely through neurologists.

After initial ascertainment, additional information from other sources was obtained from hospitalizations, neurology outpatient visits, or death certificates. Figure 2 presents the sources of diagnostic information obtained through all sources. A hospitalization, which usually included an inpatient neurologic examination, was identified for 85 of the patients. An outpatient neurologic evaluation was obtained for 72 cases and a death certificate for 54. Among those who died, autopsy confirmation was obtained on 20. The diagnosis was based solely on death certificate information for one patient, on outpatient neurologic evaluation for five patients, and on hospitalizations for seven.

The crude incidence of ALS for both sexes combined for 1985 through 1988 was 1.10 per 100 000 person-years (95% CI, 0.90 to 1.35), and the age- and sex-adjusted incidence was 1.14 per 100 000 person-years (95% CI, 0.93 to 1.40). The age-adjusted incidence for males was higher than for females, 1.27 per 100 000 person-years (95% CI, 0.95 to 1.69) and 1.03 per 100 000 person-years (95% CI, 0.075 to 1.38), respectively. The age-specific incidence for males reached five per 100 000 person-years in the 55- to 64-year-old age group and remained similar in older age groups (Table 1). In females, the rates peaked in the 65- to 74-year-old age group. Although the rates are low under the age of 45 years, the Harris County rates and proportion of younger cases are higher than those generally reported: 14% of the cases were diagnosed in patients under the age of 45 years. An inspection of these cases did not show a clustering by residency or occupation, and none of these were among the two familial incidence cases. The 14 younger cases were disproportionately black (five cases) compared with whites (eight cases) and Hispanics (one case).

The age-adjusted rates were similar for males in all ethnic groups. The rate was 1.36 per 100 000 person-years (95% CI, 0.96 to 1.87) among white males, 1.10 per 100 000 person-years (95% CI, 0.48 to 2.17) for black males, and 1.27 per 100 000 person-years (95% CI, 0.41 to 2.96) for Hispanic males. For females, the adjusted rates were 1.25 per 100 000 person-years (95% CI, 0.88 to 1.72) among whites, 0.70 per 100 000 person-years (95% CI, 0.28 to 1.44)

†1970 US total as standard.

among blacks, and only 0.08 per 100 000 person-years (95% CI, 0.002 to 0.46) among Hispanics. The rate for Hispanic females, however, was based on only one case. The numbers of Hispanic and black cases were too small to make meaningful age-specific comparisons.

The cumulative incidence of ALS to the age of 80 years for Harris County in the period 1985 through 1988 was 0.0015 for males and 0.0013 for females (Table 2). Translating this into disease odds, the risk of acquiring ALS to the age of 80 years in Harris County is 1:667 for males and 1:769 for females.

There were 70 prevalent case of ALS in Harris County on January 1, 1989 (Table 3). The overall crude prevalence was 3.04 per 100 000 population (95% CI, 2.39 to 3.86). The crude prevalence for males was 3.33 per 100 000 population (95% CI, 2.37 to 4.53) and for females, 2.74 per 100 000 population (95% CI, 1.86 to 3.89). The age- and sex-specific prevalences presented in Table 3 rise rapidly to the age of 65 to 74 years and then decline among the elderly.

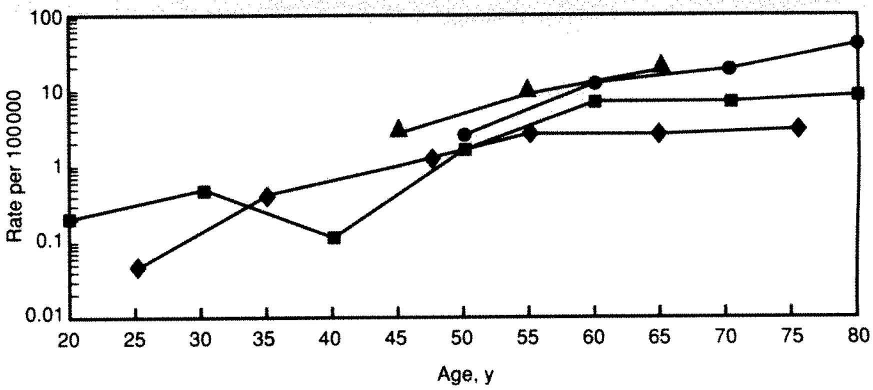

Fig 3.—Amyotrophic lateral sclerosis incidences by age for males in four studies: Harris County, Texas, 1985 through 1988 (squares); Florence, Italy, 1967 through 1976 (diamonds); Rochester, Minn, 1925 through 1984 (circles); and middle Finland, 1976 through 1981 (triangles).

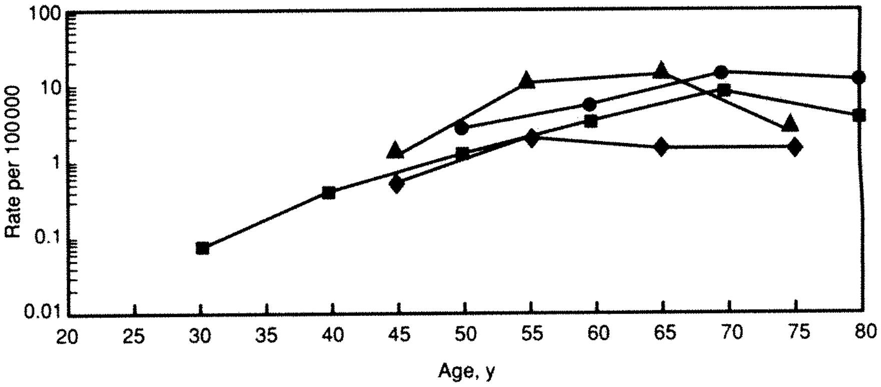

Fig 4.—Amyotrophic lateral sclerosis incidences by age for females in four studies: Harris County, Texas, 1985 through 1988 (squares); Florence, Italy, 1967 through 1976 (diamonds); Rochester, Minn, 1925 through 1984 (circles); and middle Finland, 1976 through 1981 (triangles).

COMMENT

The age-adjusted and cumulative incidence of ALS from worldwide studies, which provided the necessary age- and sex-specific information to adjust to a common standard, are presented in Table 2.[7,8,11-15] The age-adjusted rates in Harris County are intermediate among these, being higher than rates in southern Europe but somewhat lower than those in northern Europe and Rochester, Minn. Although insufficient information is presented in three other recent northern US and Canadian studies, to adjust to a common standard, the crude incidences in these populations (Lehigh, Pa, 1.52[16]; southwestern Ontario, 1.63[17]; and Nova Scotia, 1.95 per 100 000 person-years[6]) are all considerably higher than in Harris County.

The large variation in the frequency of ALS in these studies is illustrated by the odds of ALS developing to the age of 80 years given the reported age- and gender-specific rates and survival to that age. For males, the risk is 1:263 in Rochester, 1:435 in Finland, and 1:667 in Harris County, while risks in Mediterranean populations were on the order of 1:1000. For females, the risks are lower in each population except Finland, where the risk is about 1:400 for both males and females. The age- and sex-specific incidences in Figs 3 and 4 show differing patterns from the northern United States (Rochester), southern United States (Harris County), northern Europe (middle Finland), and southern Europe (Florence, Italy). In males, the Harris County rates are high under the age of 45 years but are considerably lower than Rochester and Finland rates among older men. Unlike most other studies, the Harris County rates in males do not decrease with advancing age but plateau after the age of 55 years. The Rochester rates are unique in that they increase progressively with age. The high incidence in males over 75 years old in Rochester, however, is based on only seven cases. The Harris County rates are higher in all age groups than in Florence and other southern European populations.[12-14] The patterns differ for females in that the rates decline in the oldest age group in all of the studies.

Do these patterns represent real regional differences in the incidence of ALS or do they reflect differences in case ascertainment? It is possible that the low rates from southern Europe are due to the reliance on neurologists as the sole or major source of case ascertainment in contrast to the ascertainment in Rochester, which was based on information from all sources of medical contact. Because of the size of Harris County and the diversity of medical care sources, it is possible that case ascertainment may have been less complete than in Rochester and other higher-latitude North American populations.[16,17] Although there is potentially a greater likelihood of missing cases in Harris County, the extent to which it occurred is presumed to be considerably smaller than the regional differences noted. The four sources of ascertainment employed in this study should have identified patients with ALS who were hospitalized, seen by a neurologist, on the Muscular Dystrophy Association mailing list, or dead through 1989.

If the difference between Rochester and Harris County is due to underascertainment, we would expect the relative deficit of cases in Harris County to be primarily in the older age groups. Elderly cases could be missed because of (1) comorbidity, especially dementia and cerebrovascular disease, which can make the diagnosis of ALS more difficult, (2) less frequent referral to neurologists, and (3) a shorter duration of ALS among older patients. The age-

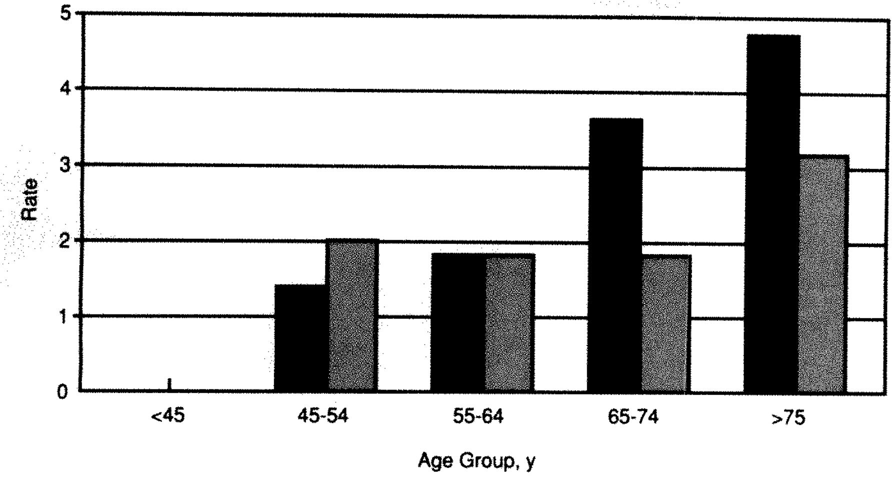

Fig 5.—Amyotrophic lateral sclerosis incidence ratio, Rochester, Minn, vs Harris County, Texas. For age group below 45 years, there were 14 cases in Harris County and none in Rochester. Solid bars indicate males; shaded bars, females. Overall adjusted rate ratios: males, 2.3; females, 1.8; and both, 2.0.

and gender-specific rate ratios between Rochester and Harris County (Fig 5) show the incidences of ALS to be about twice as high in Rochester among females in all age groups rather than confined to the older age groups. The Rochester–Harris County incidence ratio increases with age in males, which is more consistent with less complete ascertainment of cases among older males in Harris County. However, if the difference between Rochester and Harris County were solely due to underascertainment, then half of the 1985 through 1988 Harris County incidence cases in all ages and 45% of those aged 45 though 64 years would have been missed.

Another explanation for the large difference between Rochester and Harris County is that the high rates in Rochester are the chance result of rates based on only 44 cases over a 60-year period. However, this is not supported by an extension of the published Rochester ALS incidence study[7] to the remainder of Olmsted County, Minnesota, for the period 1950 through 1987 and for Rochester from 1985 through 1987, which produces an adjusted rate of 2.1 and maintains the same high rates in a different segment of the Olmsted County population (J.F.A and L. T. Kurland, MD, unpublished data, 1990). In addition, recent Canadian studies report crude rates nearly as high as the Rochester rates in Ontario[17] and higher in Nova Scotia.[6] The pattern of the rates in the United States and Europe suggests a latitudinal gradient in the incidences of ALS. If such a gradient exists, it is not as great as that for multiple sclerosis, but there may be latitudinal differences on the order of twofold. This is one of the few studies to evaluate ethnic differences in the occurrence of ALS. Although mortality studies have shown lower rates in US blacks than whites,[1,5] this difference has not been evaluated in incidence studies. Our results show similar rates in whites and blacks in Harris County. However, since there were only 14 cases among blacks in Harris County, our results do not rule out a modest decrease in blacks compared with whites.

There is some evidence that the incidence of ALS may be unusually low in Mexico. International comparisons show the mortalities in Mexico to be the lowest reported in any country.[1] A study of the incidence of ALS among government employees in Mexico City reported a rate of only 0.4 per 100 000 person-years,[15] which led to the speculation of possible Mexican resistance to ALS. The sex-specific findings of the Hispanic population in Harris County show a deficit in Hispanic females, which is the reverse of that in Mexico City, where the rate was 0.29 for males and 0.50 for females. Therefore, the question of the relative ALS incidence between whites and Hispanics remains unresolved.

This research was supported by the Muscular Dystrophy Association, Tucson, Ariz.

We are indebted to V. Appel and the Harris County neurologists and hospital administrators whose cooperation made this study possible. We also appreciate the constructive comments of Leonard Kurland, MD, David Williams, MD, and Sally A. Blakley, PhD.

Estimated Prevalence of Dementia Among Elderly Black and White Community Residents

Albert Heyman, MD; Gerda Fillenbaum, PhD; Bea Prosnitz; Kate Raiford, MSW; Bruce Burchett, PhD; Chris Clark, MD

• A stratified random sample of 83 black and 81 white community residents aged 65 years and older in a five-county area in the Piedmont region of North Carolina was evaluated for dementia, using the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition*, and the National Institute of Neurological Disorders and Stroke–Alzheimer's Disease and Related Disorders Association criteria. Of 164 subjects, 26 were found to be demented, resulting in an estimated prevalence rate of dementia in the five-county area of 16% (95% confidence interval, 7.92 to 24.08) for blacks and 3.05% (95% confidence interval, 0 to 6.91) for whites. The estimated prevalence of dementia for white women (2.9%) was similar to that for white men (3.3%), but the rate for black women was distinctly higher than for black men (19.9% and 8.9%, respectively). Blacks were more likely than whites to have a history of stroke, hypertension, and other chronic disorders that might have contributed to the development of dementia. Apart from differences in rates of institutionalization, no other relevant factors were identified that might explain the difference in the prevalence of dementia in these black and white community residents.

(*Arch Neurol.* 1991;48:594-598)

The comprehensive survey of prevalence studies of dementia presented by Jorm et al in 1987[1] showed that only two of the 47 such epidemiologic studies were concerned with dementia in elderly black populations in the United States. One of these two studies surveyed a rural area of Mississippi and showed that severe dementia was more prevalent among blacks than among whites and among women than among men.[2] The other biracial study was considerably smaller and was conducted within an inner area of Baltimore, Md, surrounding The Johns Hopkins Hospital.[3] The prevalence of dementia was found to be the same in both racial groups, but dementia caused by cerebrovascular disease tended to be more frequent among blacks. Confirmatory evidence of racial differences in the types of dementia was observed at that institution, where 144 patients with clinical diagnoses of dementia were autopsied between 1973 and 1986.[4] Among these, blacks had a significantly higher frequency of multi-infarct dementia and of dementia associated with alcoholism than did whites. White patients, on the other hand, were found to have Alzheimer's disease and Parkinson's disease more often than did blacks.

We describe the estimated prevalence of dementia among black and white elderly community residents in a five-county area in the Piedmont region of North Carolina. A higher prevalence of dementia was found among blacks than among whites, and also among black women than among black men. Cerebrovascular disease also appeared to be considerably more frequent in blacks than in whites, a factor possibly related to the increased frequency of dementia in the former group.

SUBJECTS AND METHODS

Subjects for this study were drawn from the sample members of the Duke Established Populations for Epidemiological Studies of the Elderly (EPESE)[5] project, a longitudinal study of a stratified sample of 4164 community residents aged 65 years and older on whom information is obtained annually.

A four-stage sampling design was used to obtain a probability sample of 4164 persons aged 65 years or older living in households in a five-county region in the Piedmont area of North Carolina. In this geographic area there were 506 census (1980)–defined primary units (eg, blocks, block clusters, and enumeration districts). These primary units varied in population size. Unequal probability replacement sampling, which allows primary units to be selected more than once, was used. The first sampling selection was made from these primary units, and provided 450 zones of equal population size. These zones fell in 332 distinct primary units.

At the second sampling stage one listing unit was selected from each of the 450 zones. At the third stage, the housing units within the selected listing units were listed (n = 26 183), and the expected race (black or nonblack) of each housing unit was recorded. Since by design Duke EPESE intended to oversample blacks (desiring a sample where over 50% would be black), the housing units were stratified by race. All housing units were screened to identify those with elderly residents. Finally, at the fourth stage, the Kish procedure was used to select one elderly person at random from each household in which there were residents aged 65 years and older. Of 5223 subjects selected for the sample, 4164 were successfully interviewed, yielding a response rate of 80%. Of these, 2259 (54%) were black and 1905 (46%) were nonblack. The sampling design permits development of weights, which take into account age, sex, race, geographic location, number of elderly in the household, and nonresponse, so that it is possible to project data from the Duke EPESE sample to the same age population of the five-county area for 1986 and 1987, the baseline year when data were first collected.

Information on selected demographic and health characteristics of this cohort was obtained during the baseline EPESE survey.[5]

Accepted for publication January 25, 1991.

A brief screen of cognitive function, the Short Portable Mental Status Questionnaire (SPMSQ)[6] was also administered at that time. The adjusted score of this measure of cognitive function shows little race or education bias. This testing instrument does not screen for clinical dementia or distinguish between different types of this disorder. It should also be noted that persons appearing to be cognitively impaired on the basis of this instrument are not necessarily demented; however, persons who are demented are expected to be cognitively impaired.

We capitalized on the availability of the SPMSQ scores in the Duke EPESE cohort by drawing a sample that would maximize the likelihood of locating cases of dementia in a manner that would allow the findings to be projected to the five-county older population. To facilitate efficient case finding, the SPMSQ scores were trichotomized, that is, the total EPESE sample was divided into persons with scores below the cutoff for cognitive impairment (in the original standardization sample,[6] scores below the cutoff captured half of the demented subjects), those with one point better than the cutoff, and finally, those with two points better than the cutoff. These three groups were then sorted by race and, within race, by sex and 5-year age group (Figure). Thirty Duke EPESE sample members were dropped, since they were neither black nor white (ie, Hispanic, Asian, and Native American). Eighteen others were also excluded, since their educational level was unknown and their placement on the SPMSQ with respect to cognitive impairment could not be established. The total number of persons represented in our study was, therefore, 4116.

We then selected our subjects from within each of the SPMSQ/race/sex/5-year age groups at random. Within each of the three SPMSQ categories we tried to select the same number of black men as white men, and as many black women as white women, making sure that all 5-year age groups were represented. To obtain the desired 164 subjects (83 black, 81 white), distributed in the relevant categories, 222 persons were contacted. Fifty-eight of these 222 persons declined. Of the 164 subjects who participated in this study, 30% were drawn from the unimpaired SPMSQ group, 38% from those with one point above the cutoff (hereafter called "marginal") score and 32% from those with scores indicating definite cognitive impairment.

A letter was sent to each person selected for the study explaining the nature of the survey. This was followed by a telephone call to arrange for an appointment at the subject's home where interviews were carried out by one of two trained members on our staff. Arrangements were made for each subject and informant to be seen by a neurologist (A.H.) at a locally convenient, nonthreatening site or, failing that, at home. At the initial visit with the respondent, the interviewers collected information for a related study on the sensitivity and specificity of well-established screens for dementia.[7] The results of these tests and those on the initial survey were not made available to the neurologist.

During his examination, the neurologist administered a semistructured interview to each of the 164 subjects. A medical and psychiatric history was obtained, particularly for disorders that might be related to dementia. Specific attention was paid to a history of hypertension, stroke and its sequelae, heart disease, diabetes, cancer, chronic obstructive pulmonary disease, seizures, and other neurologic or metabolic disorders. In addition, questions were asked regarding excess alcohol intake, drug abuse, and cigarette smoking. Information was also obtained on possible serious head injury. The psychiatric history included inquiry into depression and its various possible manifestations and into previous psychiatric disorders and mental retardation. A brief physical and neurologic examination was carried out to assess the general appearance of the subject, the presence of focal motor abnormalities, extrapyramidal signs, gait disorder, myoclonic jerks, and other neurologic dysfunctions. Tests were made for abnormalities in language, motor and constructional praxis, calculation, clock drawing, instrumental and physical activities of daily living, and performance on the SPMSQ screen. The alertness of the subject was assessed. Based on these measures, a diagnosis of dementia and, specifically, of Alzheimer's disease was made, using the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition*,[8] and the National Institute of Neurological Disorders and Stroke–Alzheimer's Disease and Related Disorders Association criteria.[9] The severity of the dementia, when present, was rated on the Clinical Dementia Rating scale,[10] and factors possibly related to the dementing process (eg, cerebrovascular disease, parkinsonism) were also listed.

RESULTS

Of 164 subjects examined by the neurologist (A.H.), 26 were diagnosed as having dementia (Table 1). This included 19 blacks (seven men and 12 women) and seven whites (three men and four women). Of these 26, 19 came from the group of 53 subjects whose scores were below the SPMSQ cutoff (impaired), four from the 62 whose scores were one point above the SPMSQ cutoff (marginal), and three from the 49 whose scores were two points above the SPMSQ cutoff (unimpaired). The last row of the Figure shows the SPMSQ classes that yielded these 26 demented subjects. As expected, almost all of the demented subjects (23/26) had SPMSQ scores in the definitely or marginally impaired range. The fact that three of those with unimpaired SPMSQ scores were found to have dementia attests to the fact that this screening test may produce false-negative results. It is evident that no precise cutoff point can be used to ensure the detection of all demented cases in a population survey.

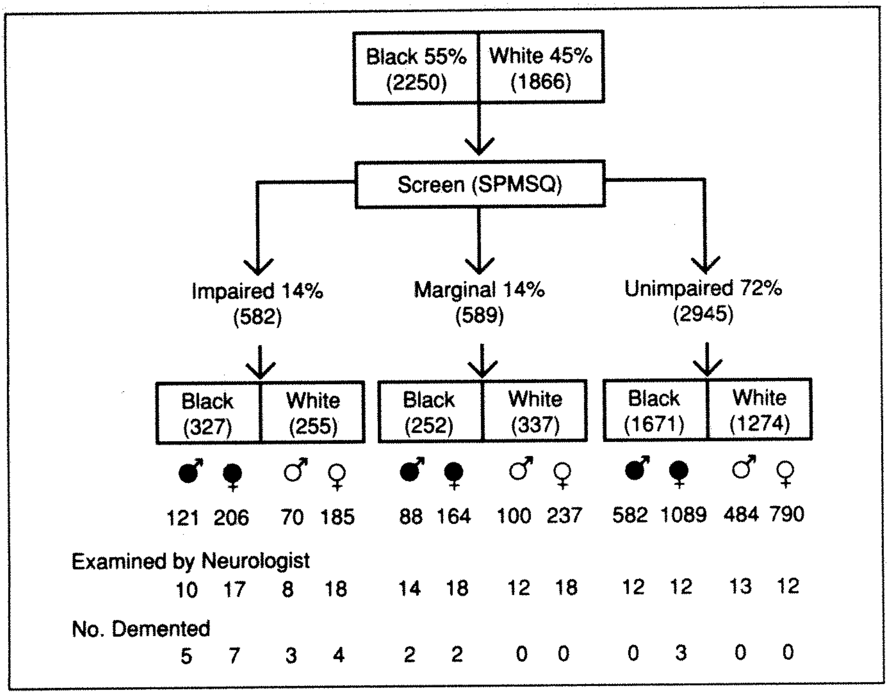
It is also of interest that only seven (26.9%) of the 26 white subjects with impaired SPMSQ scores were found by the neurologist to be demented compared with 12 (44.4%) of 27 blacks with impaired scores in this screening test (see lower two rows in the Figure). This disparity in the diagnosis of dementia in the two racial groups with impaired cognitive function led us to look for various disorders other than dementia that may have been present in the blacks and whites with impaired cognitive function.

Table 1.—Distribution of Demented Subjects

	Black	White
Probable Alzheimer's disease	12	4
Mixed or multi-infarct dementia	5	1
Systemic cancer or brain tumor	2	1
Parkinson's disease	...	1
Total	**19**	**7**

In this regard we reviewed the possibility of three major conditions related to cognitive dysfunction in the elderly: (1) age-associated memory impairment as assessed by the neurologist, and (2) depression, and (3) significant impairment in activities of daily living as assessed by a close friend or family member. The percentages of blacks with cognitive impairment but without dementia who had such disorders were 20.0% for age-associated memory impairment, 26.7% for depression, and 40% for activities of daily living compared with 16.7%, 11.1%, and 55%, respectively, in whites. These data would not support a conjecture that standards for accepting dementia among blacks were more lenient than those for whites.

The medical records for all 26 subjects were requested from their physicians and hospitals. Thirteen (50%) of them were found to have been diagnosed as having dementia by previous hospital or clinic examinations. Of the remaining 13 subjects, seven were referred to the Memory Disorders Clinic of Duke University Medical Center, Durham, NC, for evaluation by a second neurologist (C.C.) experienced in the diagnosis of dementia. There, a complete neurologic examination and a structured neuropsychologic evaluation were carried out along with appropriate laboratory studies and magnetic resonance imaging of the brain. All seven of these subjects were diagnosed as having Alzheimer's disease. Of the remaining six subjects, two died before further evaluation could be carried out, and the remaining four could not travel to the clinic because either they were confined to nursing homes or their dementing disorder was too severe.



Estimating prevalence of dementia in five North Carolina counties. Flow chart shows process for deriving the stratified random sample from the 4116 black (aged 65 years or more) and white (aged 65 years or more) subjects screened for cognitive impairment. SPMSQ indicates Short Portable Mental Status Questionnaire.

Among the 26 demented subjects, seven were classified, on the basis of the Clinical Dementia Rating scale,[10] as having severe dementia, eight as moderate, and 11 as mildly demented. The blacks and whites did not differ significantly in their ability to perform instrumental activities of daily living or personal self-maintenance tasks.

The data obtained from the subjects selected for neurologic examination were weighted to provide estimates of the prevalence rates for dementia in the black and white population aged 65 years and older in the five-county area. The total Duke EPESE sample and the subjects in this study were both classified into 60 mutually exclusive groups on the basis of their SPMSQ scores (impaired, marginal, unimpaired), race, sex, and 5-year age categories (65 to 69 years, 70 to 74 years, 75 to 79 years, 80 to 84 years, and 85 years and more). The weights developed for the total Duke EPESE sample not only took into account initial nonresponse (based on sex, age, and area of residence) but also adjusted for deliberate oversampling of blacks (from 54% in the Duke EPESE sample to 35% in the five-county area). Equivalent sample sizes (that took design effects into account) were calculated for both the Duke EPESE sample and this study. The weighted proportion of demented subjects within each of the groups in this study was then determined. This proportion was then applied to the corresponding weighted Duke EPESE sample group to obtain the estimated number of demented subjects in each of the 60 groups into which the total sample had been classified. Summation across appropriate subgroups yielded estimated numbers, which were then converted into population-relevant percentages, separately for blacks and for whites, and within these groups for men and for women. Age-based prevalence estimation is also feasible, but was not calculated because of the relatively small numbers of demented subjects ascertained in this study.

Table 1 lists the types and likely causes of dementia among the 26 cases. Probable Alzheimer's disease (diagnosis based on the National Institute of Neurological Disorders and Stroke–Alzheimer's Disease and Related Disorders Association criteria),[9] appears to be the most common cause, representing 16 of 26 cases. Mixed Alzheimer's disease and cerebrovascular disease or multiple strokes alone (multi-infarct dementia) accounts for an additional six demented subjects. Five of these six cases were black and one was white. All six of them had a history of sudden onset of a prior stroke with focal neurologic deficits associated with residual evidence of hemiplegia, aphasia, or other cerebrovascular focal signs. Two other subjects with dementia had a history of systemic cancer, another one had neuroimaging evidence of a large cystic tumor associated with diffuse, severe atrophy of the cerebral cortex. The remaining one of the 26 persons with dementia had a history of early-onset parkinsonism following encephalitis. Definite mental impairment was observed, which could be related to this illness or perhaps to an intracranial surgical operation for relief of the incapacitating extrapyramidal manifestations. In three of 16 persons with probable Alzheimer's disease, a history was obtained of secondary cases of dementia among their first- or second-degree relatives, suggesting the possibility of the familial type of this illness.

Table 2 shows the estimated prevalence rates of dementia weighted to represent the elderly population (aged 65 years or older) in the five-county area. The estimated prevalence rate of dementia was 8.9% for black men, 19.9% for black women, 3.3% for white men, and 2.9% for white women. The overall estimated prevalence rates for blacks and whites were 16% (95% confidence interval, 7.92 to 24.08) and 3.05% (95% confidence interval, 0 to 6.91), respectively. Because of the small sample sizes, the standard errors and confidence intervals are large and interpretation of the data should be cautious, particularly for the marked differences observed in prevalence by gender in the black elderly. It does seem clear, however, that overall, blacks have a much higher prevalence of dementia than do whites ($P<.002$). While the estimated prevalence of dementia is greater among black women than among black men, the difference is not statistically significant ($P<.08$) because of the small sample size. The small sample size also makes calculation of the age-related prevalence of dementia inappropriate.

Table 3 compares the history of vascular disease and diabetes (noted during the 1986 and 1987 baseline survey) among subjects diagnosed as demented with that present in the total EPESE sample of blacks and whites. A history of heart attacks, high blood pressure, diabetes, and stroke was reported more often by blacks with dementia than by whites with this cognitive disorder. The fact that blacks in general (and particularly black women) were much more likely than whites to give a history of hypertension and diabetes suggests that these conditions may be implicated in the higher proportion of vascular dementia (mixed or multi-infarct dementia) noted among the black subjects.

COMMENT

The results of our study confirm those reported by Schoenberg et al[2] who also

screened a large southern biracial rural community for dementia. That study, however, examined both household and institutionalized persons and reported only severely demented cases. Both their study and this one found a higher prevalence of dementia among blacks than whites, and among black women compared with black men. On the other hand, the relatively small study of an inner-city biracial community reported by Folstein et al[8] failed to show any significant differences in the frequency of dementia in the two racial groups. That study did, however, show that demented blacks were more likely than whites to have cerebrovascular disease associated with dementia—results similar to our own. We did not confirm their findings, however, that multi-infarct dementia was more common than Alzheimer's disease among blacks. Confirmatory evidence of racial differences in dementia has been reported in studies of death certificates[11] that showed blacks to have a higher reported prevalence of dementia at death than whites, and in an autopsy series[4] (admittedly not a random sample) that found that dementia was twice as prevalent among blacks as among whites.

The differences in the prevalence of dementia between blacks and whites noted in our study are substantial and statistically significant. The question arises whether factors in the design or procedural methods of the study could account for such differences. The risk of drawing major conclusions from the relatively small sample used in this study has been commented on earlier, and the need for confirmatory studies in larger biracial populations is evident. The question also arises as to whether the differences may be related to an earlier age of onset of this disorder or to a less progressive course of the illness among blacks. Unfortunately, the number of cases of dementia in this study are too small to provide such data. There is, moreover, little, if any, information in the literature on the age of onset of dementia among cases of vascular dementia compared with subjects with Alzheimer's disease or those with dementia caused by other diseases. Precise information on the age of onset of the dementing process in any of these groups of cases is difficult to obtain, since it depends largely on the observations of the subject's spouse or other caregivers. Other factors that might account for the differences in the observed prevalence rates are considered below.

The fact that the whites in this community are more likely than blacks to institutionalize their cognitively impaired family relatives may help to explain the lower prevalence rates of dementia among the white noninstitutionalized residents. One- year follow-up of the Duke EPESE sample indicates that there is a higher annual rate of nursing home entry among whites (3.1%) than among blacks (2.1%). With a cap of approximately 5% on nursing home beds in this area, roughly three quarters of the beds are occupied by whites and one quarter by blacks, ie, the 5% can be divided approximately into 3.75% white and 1.25% black residents. National estimates of 50% for the prevalence of dementia among nursing home residents would suggest that 1.8% of these whites and 0.6% of these blacks might be demented. This would not fully explain the lower rate of dementia found among white community residents. So, while the differential rate of institutionalization may modify the black-white difference in dementia prevalence by perhaps 1%, it certainly does not close the gap.

It has been suggested[12] that the level of education (probably as a surrogate for other factors) may relate to the presence of dementia. Blacks in our study have a lower level of education and this, in some way, could be a factor explaining the difference in the prevalence rate of dementia in the two racial groups. On analysis, however, no relationship was found between level of education and the presence of dementia in this cohort.

It has also been suggested that racial differences in survival rates could be implicated in our observations on the estimated prevalence of dementia in this community. In the general US population blacks are known to be at a higher risk for death than whites prior to age 75 years, but the reverse has been observed after this age. A decrease in the death rate among blacks in the older age groups could possibly account for a higher prevalence rate of dementia. However, in the Duke EPESE sample, the age pyramid for blacks is comparable with that for whites. For this group, differential survival does not seem to explain the findings.

It is possible that blacks and whites may have differed in the extent to which they participated in the study. Analysis of refusal rates in this survey (Table 4) showed that there was no major difference in participation between blacks and whites. The cognitively impaired do not appear to have been unduly shielded. Indeed, refusal was lowest for the most cognitively impaired and was particularly low among cognitively impaired white women. Thus, this factor does not appear to be important in explaining the racial differences in prevalence rates for dementia observed in this study.

The prevalence rate of dementia (3.05%) in whites 65 years of age or older in our study is similar to that (3.5%) described by Kokmen et al[13] in the largely white community of Rochester, Minn. That investigation was based on information available in local medical records, but the observed rates are considered by the investigators to be comparable with those obtained by most population surveys. In a recently reported survey of 3623 white East Boston, Mass, community residents aged 65 years and older, however, an unusually high prevalence rate of 10.3% for probable Alzheimer's disease was estimated.[14] However, few of the elderly residents from that location had been institutionalized.

As mentioned above, the fivefold higher rates we observed in the blacks compared with the whites may be related to a history of stroke and hypertension that was present in a significant proportion of the blacks. The extent to which these vascular illnesses contributed to the development of dementia in this racial group cannot be determined without postmortem examination of the brain. As stated earlier, black and white demented subjects did not differ significantly in their ability to perform instrumental or physical activities of daily living, suggesting that comparable objective impairment criteria were indeed used in identifying dementia. Further, all of the subjects diagnosed as having dementia in the field study and for whom additional diagnostic information was available from prior records or subsequent examination by another physician were found to have this disorder. Therefore, there seems little reason to doubt the accuracy of the overall diagnosis of dementia in this group.

This study was supported in part by the National Institute of Aging, Bethesda, Md, contract No. AG42110 in support of the Established Populations for Epidemiological Studies of the Elderly (Duke University Medical Center, Durham, NC).

We thank Max Woodbury, PhD, MPH, who provided advice and developed the techniques permitting information from sample subjects to be projected to the five-county area.

Association of Decreased Paternal Age and Late-Onset Alzheimer's Disease

An Example of Genetic Imprinting?

Lindsay A. Farrer, PhD; L. Adrienne Cupples, PhD; Linda Connor; Philip A. Wolf, MD; John H. Growdon, MD

• Several studies have identified advanced maternal age as a risk factor for Alzheimer's disease. This study evaluated maternal and paternal age at birth of 237 patients with Alzheimer's disease, each of whom was matched to five control subjects based on sex, year of birth, survival age, and location of residence. It was found that decreased paternal age substantially increased the susceptibility to the common form of Alzheimer's disease that occurs after the age of 67 years, whereas advanced maternal age had a negligible effect on risk of Alzheimer's disease. The higher incidence of late-onset Alzheimer's disease among persons born to younger fathers is consistent with a genetic imprinting mechanism involving DNA methylation. The proposed model postulates a role for environmental agents in the pathogenesis of Alzheimer's disease and accounts for families that show an aggregation of cases but no apparent pattern of inheritance.

(*Arch Neurol.* 1991;48:599-604)

Alzheimer's disease (AD) is a neurodegenerative dementing illness characterized by pervasive defects in cognition and personality; it affects an estimated 10% of the population older than 65 years.[1] The basic etiology of AD is unknown, although advanced age and a positive family history of dementia are two predominant risk factors. Several environmental agents, including head injury, slow viruses, and aluminum, have been implicated but have not yet been proved to play a role in the etiology and pathogenesis of AD.[2-7]

Numerous studies postulating a link between AD and Down syndrome[8-12] prompted investigations of maternal age at the birth of the subject, which has been identified as a strong risk factor for Down syndrome[13] and, thus, as a potential risk factor for AD. Four studies provided evidence that mothers of patients with AD are substantially older when their child is born than are mothers of control subjects,[14-17] whereas four other studies did not find this association.[18-21]

This study was undertaken to determine whether an association between AD and parental age at birth of the subject could be demonstrated in a comparatively large number of consecutively ascertained and rigorously diagnosed cases of AD, each of these patients being compared with five nondemented control subjects from the Framingham Study matched for sex, year of birth, and survival age. We hypothesized that if there is an effect of parental age on the incidence of AD, it would not likely be detectable in familial cases of AD (designated FAD) if liability for illness in these cases is caused by inherited defects that were already present in the parents' germ cell line before conception. Second, a parental age effect, if it exists, may be maternal or paternal in origin, depending on the particular genetic or nongenetic factors underlying the effect. For example, the incidence of many single-gene disorders is associated with advanced paternal age, whereas certain chromosomal aneuploidies are more prevalent in children born to older mothers.

SUBJECTS AND METHODS

Subjects

Genealogical data and family history of dementia were collected for 301 unrelated probands examined consecutively in the Memory Disorders Unit of the Massachusetts General Hospital, of whom 251 met National Institute for NINCDS-ADRDA criteria[22,23] for probable AD. Protocols for patient evaluation, informant interviews, and administration of questionnaire instruments are described elsewhere.[24] Preliminary data analysis showed that 14 of the probands with probable AD were missing parental age data for one or both parents, and these individuals were subsequently dropped from further analysis. The final total sample with AD from the Memory Disorders Unit consisted of 237 subjects (95 men and 142 women) born between 1895 and 1940. The mean (± SD) age at onset of dementia was 67.2±8.4 years (range, 42 to 86 years).

Control data were obtained from 8723 participants of the Framingham Study.[25] Approximately 5209 of these persons are adult residents of the town of Framingham, Mass, who were enrolled in a longitudinal study of health in 1950. Most of the original study members were the 4469 respondents of 6510 persons selected in a two-thirds stratified sampling of the adult population of the town. Another portion of this cohort, 740 men and women, were volunteers who were spouses of persons in the sample. Pertinent medical history, psychological, family history, lifestyle, and demographic data have been systematically collected over biennial examinations during this time. The remainder of the

Framingham Study population comprises children of the original cohort who currently are participating in a parallel longitudinal study known as the Offspring Study. Dates of birth for parents of control subjects whose parents were also Framingham Study participants were obtained from their parents' records. Otherwise, this information was obtained from another database, which stored parental data collected in a previous study described by Schildkraut et al.[26]

For analytical purposes, the 237 subjects with AD were matched with five controls based on sex, year of birth, and a survival age variable. To improve the power of our statistical analyses by minimizing the SEs in the control group, we chose five controls (rather than one) for every case. The Framingham pool of subjects would not permit more controls per case without loss of cases owing to an insufficient number of matching controls. Furthermore, it has been shown that the increase in power is not substantial beyond four controls per case.[27] Specifically, age at onset of dementia in the patient with AD was matched with the censoring age (current age or age at death) in the control subjects. Control subjects were not demented at the time of censoring. If an insufficient number of controls were found to meet all three criteria, the matching algorithm selected controls who were born within 3 years of the case or whose censoring age was up to 3 years greater than the onset age of the case. With five matched controls for every case, the total control sample numbered 1185.

Analytical Procedures

Parental ages (age of mother and father, respectively, at time of subject's birth) were compared between AD cases and controls in two ways. In one method, mean maternal and paternal ages were calculated for each set of five matched controls and compared with the corresponding values for the cases using a paired-comparison *t* test, which tests whether the mean of the differences between the matched pairs is significantly different from zero.[28] Subgroup analysis was carried out by dividing subjects based on the mean onset age of AD (older or younger than 67.2 years) and family history of dementia of the AD cases, two criteria that may define distinct subtypes of AD.[29-31] Stratification by family history is less straightforward. A positive family history of dementia in a relative does not prove that the proband was genetically predisposed to AD because, for example, dementia could occur in two siblings by chance. Family and genetic studies suggest that AD in a proportion of cases may be transmitted as an autosomal dominant trait, particularly if onset occurs before the age of 65 years.[32] Thus, a case was defined as FAD only if either parent had AD. All other cases were considered to be sporadic (designated SAD).

To examine the interrelationship of paternal and maternal ages on development of AD, parental ages were also evaluated using conditional logistic regression for case-control designs.[33] This design permits the joint analysis of the effects of maternal and paternal ages and their interactions with other covariates on the development of AD to disentangle the correlation of mothers' and fathers' ages ($r = .77$ for AD cases and $r = .71$ for controls). These analyses were carried out using the PHGLM procedure in SAS, as described in the manual for an application to conditional logistic models with one case per matched set.[34]

* AD indicates Alzheimer's disease; OR, odds ratio for AD developing for every 5-year increase in maternal or paternal age; CI, confidence interval (for odds ratio); NS, not significant; FAD, familial AD; and SAD, sporadic AD. Numbers are sample size where the proportion of AD cases is one sixth of the sample.

RESULTS

The mean maternal and paternal ages at the time of the subject's birth were almost identical for patients with AD and control subjects (Table 1). However, at the time of the subject's birth, fathers of late-onset AD cases were significantly younger than fathers of control subjects by an average of 2.2 years ($P = .003$). A similar trend was observed for maternal age, but the difference was only 1.3 years ($P = .035$). Maternal and paternal ages were not significantly different among AD cases and controls in FAD or SAD subgroups. Stratification of subjects with AD and their corresponding matched controls by onset age group and family history showed that the paternal age effect is present only in patients with late-onset AD whose parents did not have AD. The difference in maternal age in this subset is smaller and only borderline significant ($P = .050$). Older paternal age among controls was observed in the group with late-onset FAD, but the difference was not significant because the sample size was only half as large as the group with late-onset SAD.

Conditional logistic models confirmed the presence of a significant paternal age effect in late-onset cases and suggests that the observed maternal age effect in the univariate analysis is probably due to the high collinearity between mothers' and fathers' ages (Table 2). Moreover, examination of the coefficients for this model reveals that paternal age has a 21-fold stronger effect than maternal age on the predicted outcome of AD vs control. The comparatively weaker maternal age effect shows a slight positive association with risk of AD. Relative risk of late-onset AD as a function of maternal and paternal age is shown in Fig 1.

COMMENT

The results of this study suggest that paternal age and, to a much lesser degree, maternal age influence an individual's susceptibility to the common form of AD that occurs after the age of 67 years. Moreover, in contrast to other studies that found an association between AD and advanced maternal age,[14-17] the data reported herein indicate that decreased paternal age increases the risk for AD. Our findings are based on data from 237 rigorously diagnosed and consecutively ascertained patients with AD who were matched to five control subjects each based on the year of birth, sex, survival age, and residence.

The mean parental ages for the cases and controls are in agreement with comparable data from other studies (Table 3). Careful inspection of these data revealed that parental ages in the control group in the Japanese study[17] were noticeably low, and the median parental ages of AD subjects in the original University of Washington study[14] were much higher than in other case series. Biased selection of cases and/or controls, social differences in childbearing patterns, or sampling error may account for these differences.

Failure to detect an association between AD and decreased paternal age in previous studies can be explained by several reasons. First, the effect was demonstrable only after removing early onset cases from the study population. Second, the number of late-onset AD cases in this study (124) exceeded the total subject population with AD in all but two other studies,[16,21] one of which found only a marginal advanced maternal age effect and did not examine paternal age.[16] Equal case and control samples of at least 220 persons each are required to detect a mean difference of 2.0 ± 7.5 years, assuming 5% error and 80% power. Third, none of the previous investigations of parental age accounted for censoring bias of controls, thus ignoring the possibility that some of these subjects may suffer dementia later in life. Fourth, this study is the first to assess maternal and paternal ages simultaneously using statistical methods to adjust for collinearity between mothers' and fathers' ages.

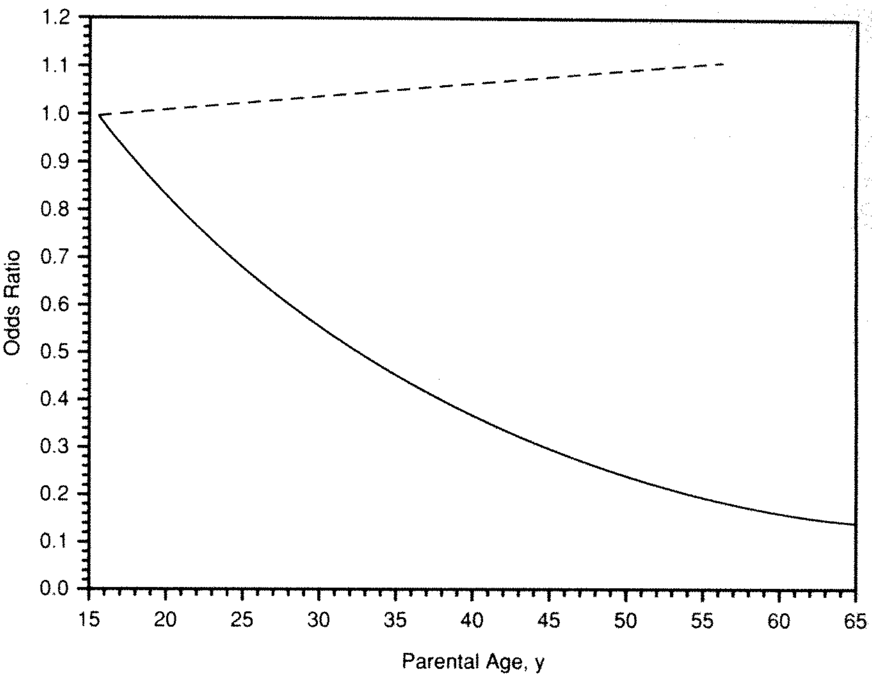

Fig 1.—Relative risk of late-onset Alzheimer's disease developing according to mother's (broken line) and father's (solid line) age at the time of birth. Separate risk curves for maternal and paternal age were calculated from the conditional logistic regression model for subjects with late-onset disease and matched controls (Table 2). The odds ratio equation for maternal age is $\mathrm{OR} = \exp(0.0021 \times \text{maternal age})$ where exp refers to the exponential function; the equation for paternal age is $\mathrm{OR} = \exp(-0.044 \times \text{paternal age})$. The odds ratio at the age of 15 years was standardized to 1.

However, there are several caveats in the interpretation of our findings. First, the observation of advanced maternal age in AD cases in other studies needs to be reexamined in those and other populations using a sufficient number of patients with AD and appropriately matched controls. All of the published studies of parental age, including our own, were performed on a clinic-based series of subjects, which may not be representative of patients with AD in the general population. Longitudinal studies of the dementia status of a large cohort of elderly subjects, including their siblings,[35] would allow alternative study designs of parental age, including unbiased evaluation of birth order. Second, further examination of the results in Table 1 suggests that parental ages are not different between early-onset and late-onset AD cases. However, it is misleading to conclude that there are no parental age differences between early-onset and late-onset AD cases simply because the mean ages are the same. To compare these two groups appropriately, the cases would need to be matched for year of birth. In addition, controls matched to late-onset AD cases have significantly greater maternal ($t = 2.45$, $P = .015$) and paternal ($t = 4.91$, $P < .001$) ages than controls matched to early-onset cases. Although these patterns may suggest a biased sample of control subjects in the late-onset group, the parental age difference among controls is more likely related to secular trends in year of birth. Early-onset cases and controls had a mean birth year of 1923 (range, 1907 to 1940), which is significantly greater than the mean of 1911 (range, 1895 to 1919) for the late-onset subjects ($t = 16.31$, $P < .001$). The mean parental ages for the control groups are consistent with secular trends for parental age in the Framingham cohort (Fig 2). Even though this secular trend persists, our subjects are matched on year of birth, and thus, our conclusions should not be affected by this secular trend. Third, the results of our study suggest, but do not rule out, that the parental age effect has a uniquely paternal origin. If the effect is partially or totally maternal, several other hypotheses regarding the maternal-fetal environmental (eg, toxic or infectious exposure and maternal immune response) or maternal (cytoplasmic or mitochondrial) inheritance must be considered.

The studies showing significantly greater maternal age in AD cases are puzzling because the premise underlying the hypothesis linking maternal age to both Down syndrome and AD is not entirely valid. The frequency of chromosomal nondisjunction, the biological mechanism causing most cases of Down syndrome and other trisomic conditions, increases with maternal age.[36]

Table 3.—Maternal and Paternal Ages Among AD Cases and Controls Reported in Previous Studies*

	Cases			Controls			
Study	**No.**	**Maternal Age, y**	**Paternal Age, y**	**No.**	**Maternal Age, y**	**Paternal Age, y**	**Comments**
Cohen et al[14]	80	35.5 ± 1.4	38.0 ± 1.4	590	27.0	. . .	Median values reported; all controls born in 1907
Whalley et al[15]	69	30.6 ± 0.7	32.2 ± 0.8	207	28.6 ± 0.4	30.8 ± 0.5	Each case was date-of-birth matched with 3 controls

*AD indicates Alzheimer's disease. Values are mean ± SE unless otherwise noted.

However, chromosome studies of subjects with AD do not show any consistent abnormal findings other than those associated with normal aging.[37] Thus, there is no cytogenetic basis for increased frequency of AD with advanced maternal age. Furthermore, the advanced maternal age hypothesis presumes that the defect underlying the clinical, neuropathological, and familial traits common to AD and Down syndrome is on chromosome 21. However, the only direct evidence implicating chromosome 21 in the pathogenesis of AD is identification of genetic linkage between the gene for a rare, early onset, autosomal dominant form of AD and anonymous DNA markers that are located outside of the chromosomal region associated with Down syndrome,[38-41] as well as two studies showing triplication of chromosome 21 genes in randomly selected patients with AD,[42,43] but these latter results have been disputed.[44-46]

GENETIC HYPOTHESIS FOR PATERNAL AGE EFFECT

An explanation of the association between AD and decreased paternal age must account for the observation of this relationship occurring only in late-onset cases and the fact that transmission of uniquely paternal risk factors to offspring occurs only through the germ cell line. Thus, exposure to environmental agents is unlikely the cause of the paternal age effect. A growing body of evidence suggests that the early onset form of AD is an autosomal dominantly transmitted trait,[32] whereas AD in a proportion of individuals with late-onset disease may have other causes.[24,31] Lack of a paternal age effect among patients with SAD probably indicates that our classification scheme for FAD and SAD is not robust. Distinction of noninherited cases will continue to be difficult until a genetic or other biological marker is identified.

Although persons with SAD presumably have not inherited an abnormal AD gene per se, they may still inherit increased predisposition to disease through a particular parent. This type of transmission is called "genetic imprinting."[47] It has been postulated that imprinting does not cause a mutation in the DNA, but rather an alteration in the function of DNA that may last the lifetime of the individual.[47] Compelling evidence has been accumulating from experimental studies in transgenic mice that gene activity can be altered in alleles originating from a particular parent by methylation or demethylation of DNA.[48-52] Experimental evidence in human cells growing in culture indicates that there is a concomitant loss of the number of methylated sites on DNA and gene expression with increasing numbers of cell divisions. This age-related phenomenon is accelerated when even young cells are treated with azacytidine, a compound that enhances demethylation.[53] Sperm DNA, which is highly methylated except for a few spared genes,[49] is more likely to have undergone progressive demethylation than DNA in an ovum from a woman of the same age because male germ cells undergo many more cell divisions than female germ cells. To illustrate this point, at sexual maturity female germ cells have undergone two divisions. It has been estimated that the number of cell divisions in spermatogenesis is 30 at puberty and increases at the rate of 23 per year thereafter.[54] Thus, at the age of 35 years, for example, male germ cells have undergone approximately 540 divisions.

How might genomic imprinting be responsible for cases of late-onset AD, and how would it account for the tendency for these subjects to have younger fathers at the time of their birth? It has been postulated that AD is a sequela of the aging process.[55-57] Numerous genes

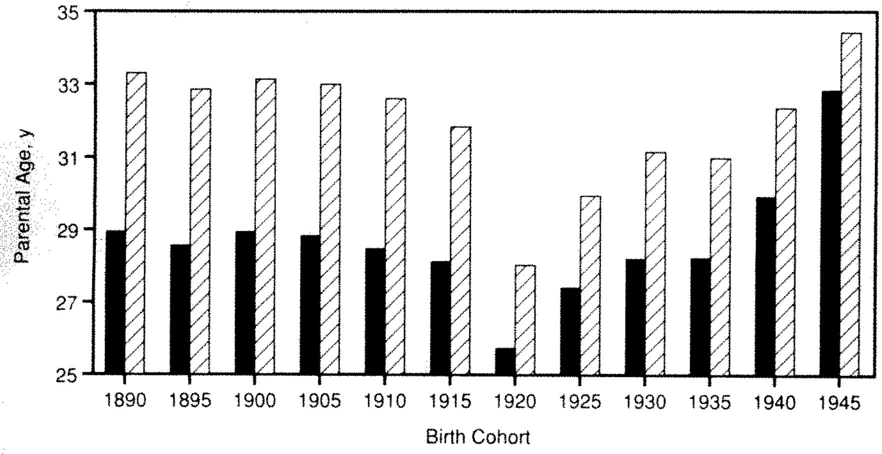

Fig 2.—Mean maternal (solid bars) and paternal (shaded bars) ages among 7559 subjects in the Framingham Study born between 1890 and 1949 by 5-year cohorts.

are likely involved in aging,[58] and it is conceivable that alteration in the expression of one or more of them could result in the AD phenotype. Normal development of the central nervous system depends on appropriately timed expression of many genes from embryonic life until adulthood. Complex systems like the brain must have a myriad of genetic regulation mechanisms, and evidence from studies of other inherited neurological diseases that show parental sex effects, including Huntington's disease, myotonic dystrophy, and neurofibromatosis, suggests that DNA methylation may be involved.[47,59,60]

Let us presume that most persons will suffer AD if they do not succumb to other causes before they reach the age at which they would have onset of symptoms, and that pathogenesis can be accelerated or retarded by methylation and demethylation of the genes involved. If protection against AD requires expression of certain genes early in life, it follows that a person born to a young father is more likely to have a higher proportion of methylated and hence inactive genes, including genes that, when active, protect against AD, than a person born to an older father. Therefore, this person has a higher risk of AD developing later in life. However, there must be an additional mechanism for the determination of onset, which usually occurs after the age of 65 years. Thus, this model predicts not only that the pathogenesis of AD begins early in life, but also that a second event, such as demethylation of the same or another set of genes later in life, is necessary for disease to occur. The involvement of environmental agents or other nongenetic risk factors in the second event would explain the low concordance rate for AD among monozygotic twins.[61-64]

A genetic imprinting model for AD would be consistent with the sporadic nature of most cases if the probability of having demethylated genes, and hence protection against AD, is high or if methylation is necessary but not sufficient for development of disease. This hypothesis could also account for families that show an aggregation of cases but no apparent transmission or inheritance pattern,[32] because the methylation states of identical alleles among parents and offspring would not necessarily be the same. However, we emphasize that the above arguments implicating DNA methylation are speculative. It is reasonable to expect that an imprinting mechanism other than methylation contributes to the pathogenesis of AD, but little is known about these processes.

This work was supported in part by grants NS-17950, AG06865, and P50 AG05134 and contract HC-38038 from the National Institutes of Health, Bethesda, Md.

We are indebted to Richard H. Myers, PhD, for helpful discussions on genetic imprinting, Dan Kiely, MS, MPH, for technical assistance, and Jemma Williams for preparing the manuscript.

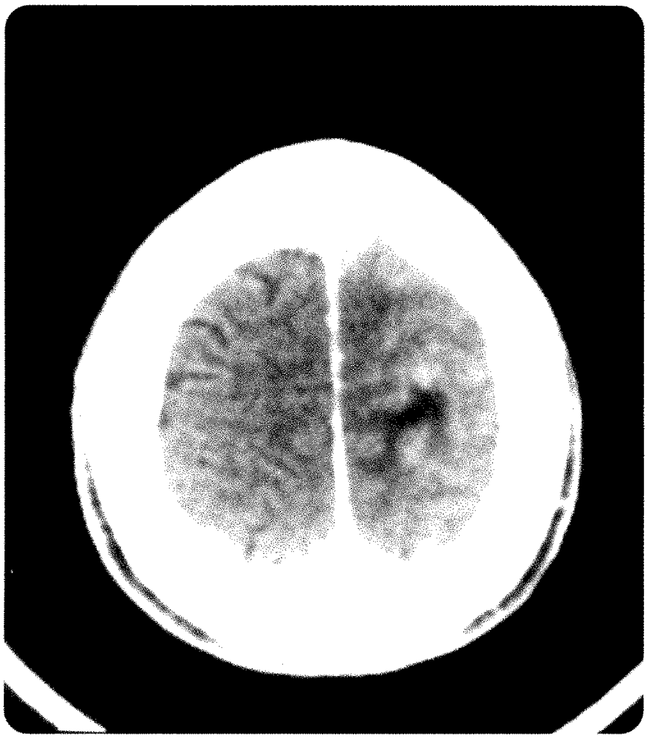
THE DECISION IS YOURS.

COMPARE.

THE CASE: A 40-year-old man presented with a 2-month history of involuntary muscle contractions of the right arm and mild weakness of the left leg.

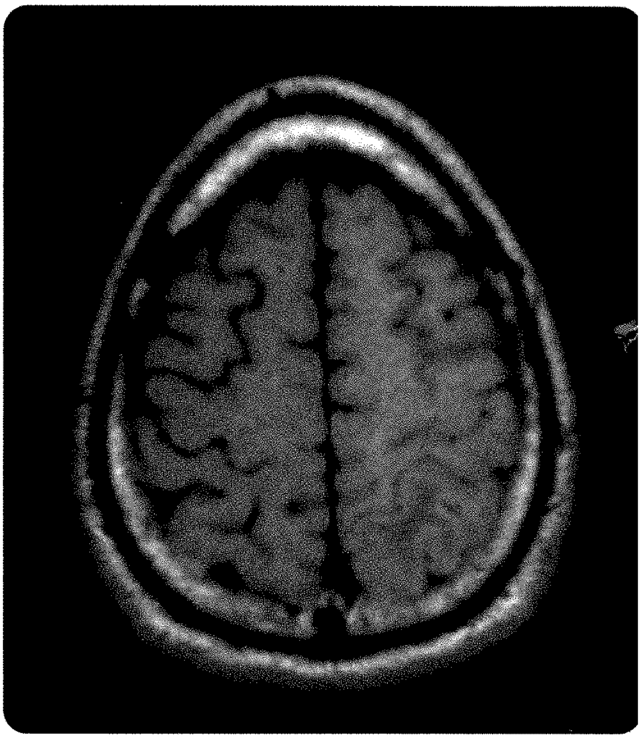
First there was CT.



Contrast CT scan shows an area of low attenuation in the left parietal lobe. A questionable focus of contrast is seen, but this may represent cerebral cortex.

Images courtesy of Michael R. Ross, MD, Stanford University Medical Center, Stanford, California

Then MRI.



T1-weighted (TR 800/TE 20) unenhanced MR image, obtained with a 1.5-T imager, shows subcortical hypointensity in the left posterior parietal lobe. The surrounding sulci appear to be compressed, but a mass is not clearly appreciated.

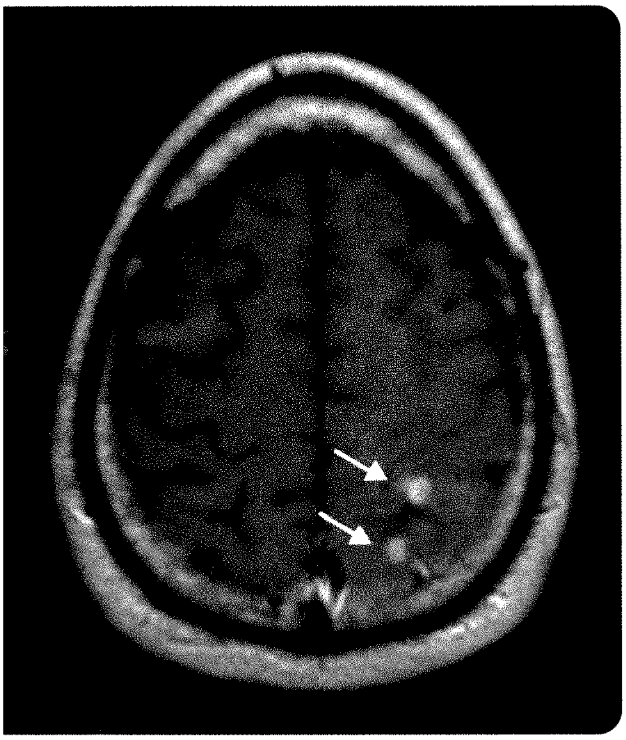
AND CONTRAST.

ow, *Magnevist*®-
nhanced MRI lets
ou see even more.

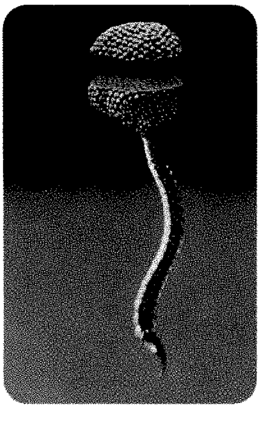


1-weighted (TR 800/TE 20) image enhanced with AGNEVIST® injection reveals two discrete nodules rrows). This nodular enhancement is highly uggestive of a primary brain tumor, which was onfirmed upon biopsy to be an astrocytoma.

Magnevist®
(gadopentetate
dimeglumine 469.01 mg/mL)
INJECTION

NOTHING LOCATES LESIONS BETTER

Please see brief summary of prescribing information for MAGNEVIST® injection on last page of this advertisement.



Well tolerated[1] In clinical trials, the most common adverse reactions reported were headache (8.7%) and injection-site coldness/localized coldness (4.8%). The majority of headaches were transient and of mild to moderate severity. In clinical trials, 15% to 30% of patients experienced an asymptomatic transient rise in serum iron; hypotension and anaphylactoid reactions have occurred in less than 1% of the patients. The safety of MAGNEVIST® injection in patients with hemolytic disorders has not been studied.

REFERENCE: 1. Data on file, Berlex Laboratories, Inc.

BRIEF SUMMARY

INDICATIONS AND USAGE

MAGNEVIST® Injection is indicated for use with magnetic resonance imaging (MRI) in adults and children (2 years of age and older) to provide contrast enhancement in those intracranial lesions with abnormal vascularity or those thought to cause an abnormality in the blood-brain barrier. MAGNEVIST® Injection has been shown to facilitate visualization of intracranial lesions including but not limited to tumors.

MAGNEVIST® Injection is also indicated for use with MRI in adults and children (2 years of age and older) to provide contrast enhancement and facilitate visualization of lesions in the spine and associated tissues. There is, however, only limited clinical experience in children for this indication.

CONTRAINDICATIONS

None known.

WARNINGS

The accepted safety considerations and procedures that are required for magnetic resonance imaging are applicable when MAGNEVIST® Injection is used for contrast enhancement. In addition, deoxygenated sickle erythrocytes have been shown in *in vitro* studies to align perpendicular to a magnetic field which may result in vaso-occlusive complications *in vivo*. The enhancement of magnetic moment by gadopentetate dimeglumine may possibly potentiate sickle erythrocyte alignment. MAGNEVIST® Injection in patients with sickle cell anemia and other hemoglobinopathies has not been studied.

Patients with other hemolytic anemias have not been adequately evaluated following administration of MAGNEVIST® Injection to exclude the possibility of increased hemolysis.

Hypotension may occur in some patients after injection of MAGNEVIST® Injection. In clinical trials two cases were reported and in addition, there was one case of a vasovagal reaction and two cases of pallor with dizziness, sweating and nausea in one and substernal pain and flushing in the other. These were reported within 25 to 85 minutes after injection except for the vasovagal reaction which was described as mild by the patient and occurred after 6-1/2 hours. In a study in normal volunteers one subject experienced syncope after arising from a sitting position two hours after administration of the drug. Although the relationship of gadopentetate dimeglumine to these events is uncertain, patients should be observed for several hours after drug administration.

Magnevist®
(gadopentetate dimeglumine 469.01 mg/mL)
INJECTION

PRECAUTIONS - General

Diagnostic procedures that involve the use of contrast agents should be carried out under direction of a physician with the prerequisite training and a thorough knowledge of the procedure to be performed.

In a patient with a history of grand mal seizures, MAGNEVIST® Injection was reported to induce such a seizure.

Since gadopentetate dimeglumine is cleared from the body by glomerular filtration, caution should be exercised in patients with severely impaired renal function.

The possibility of a reaction, including serious, life-threatening, fatal, anaphylactoid or cardiovascular reactions or other idiosyncratic reactions should always be considered (see ADVERSE REACTIONS) especially in those patients with a known clinical hypersensitivity.

Animal studies suggest that gadopentetate dimeglumine may alter red cell membrane morphology resulting in a slight degree of extravascular (splenic) hemolysis. In clinical trials 15-30% of the patients experienced an asymptomatic transient rise in serum iron. Serum bilirubin levels were slightly elevated in approximately 3.4% of patients. Levels generally returned to baseline within 24 to 48 hours. Hematocrit and red blood cell count were unaffected and liver enzymes were not elevated in these patients. While the effects of gadopentetate dimeglumine on serum iron and bilirubin have not been associated with clinical manifestations, the effect of the drug in patients with hepatic disease is not known and caution is therefore advised.

When MAGNEVIST® Injection is to be injected using plastic disposable syringes, the contrast medium should be drawn into the syringe and used immediately.

If nondisposable equipment is used, scrupulous care should be taken to prevent residual contamination with traces of cleansing agents.

Repeat Procedures: If in the clinical judgment of the physician sequential or repeat examinations are required, a suitable interval of time between administrations should be observed to allow for normal clearance of the drug from the body.

Information for Patients:

Patients receiving MAGNEVIST® Injection should be instructed to:

1. Inform your physician if you are pregnant or breast feeding.
2. Inform your physician if you have anemia or any diseases that affect red blood cells.

LABORATORY TEST FINDINGS

Transitory changes in serum iron and bilirubin levels have been reported in patients with normal and abnormal liver function (See PRECAUTIONS - General).

CARCINOGENESIS, MUTAGENESIS, AND IMPAIRMENT OF FERTILITY

No animal studies have been performed to evaluate the carcinogenic potential of gadopentetate dimeglumine.

Gadopentetate dimeglumine did not evoke any evidence of mutagenic potential in the Ames test (histidine-dependent *Salmonella typhimurium*) nor in a reverse mutation assay using tryptophan-dependent *Escherichia coli*. Gadopentetate dimeglumine did not induce a positive response in the (C3H 10T1/2) mouse embryo fibroblast cellular transformation assay, nor did it induce unscheduled DNA repair synthesis in primary cultures of rat hepatocytes at concentrations up to 5000 μg/mL. However, the drug did show some evidence of mutagenic potential *in vivo* in the mouse dominant lethal assay at doses of 6 mmol/kg, but did not show any such potential in the mouse and dog micronucleus tests at intravenous doses of 9 mmol/kg and 2.5 mmol/kg, respectively.

The results of a reproductive study in rats showed that gadopentetate dimeglumine when administered in daily doses of 0.1-2.5 mmol/kg, did not cause a significant change in the pregnancy rate in comparison to a control group. However, suppression of body weight gain and food consumption and a decrease in the mean weights of testis and epididymis occurred in male rats at the 2.5 mmol/kg dose. In female rats a decrease in the number of corpora lutea at the 0.1 mmol/kg dose and the suppression of body weight gain and food consumption at the 2.5 mmol/kg dose were observed.

In a separate experiment, 16 daily intravenous injections were administered to male rats. At a dose of 5 mmol/kg of gadopentetate dimeglumine, spermatogenic cell atrophy was observed. This atrophy was not reversed within a 16-day observation period following the discontinuation of the drug. This effect was not observed at a dose of 2.5 mmol/kg.

PREGNANCY CATEGORY C.

Gadopentetate dimeglumine has been shown to retard development slightly in rats when given in doses 2.5 times the human dose, and in rabbits when given in doses of 7.5 and 12.5 times the human dose. The drug did not exhibit this effect in rabbits when given in doses 2.5 times the human dose. No congenital anomalies were noted in either species.

There are no adequate and well-controlled studies in pregnant women. MAGNEVIST® Injection should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS

C^{14} labelled gadopentetate dimeglumine was administered intravenously to lactating rats at a dose of 0.5 mmol/kg. Less than 0.2% of the total dose was transferred to the neonate via the milk during the 24-hour evaluation period. It is not known to what extent MAGNEVIST® Injection is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when the drug is administered to a nursing mother and consideration should be given to temporarily discontinuing nursing.

PEDIATRIC USE

Safety and efficacy in children under the age of 2 years have not been established. (See Indications and Usage and Dosage and Administration sections).

ADVERSE REACTIONS

The most commonly noted adverse experience is headache with an incidence of 8.7%. The majority of headaches are transient and of mild to moderate severity. In 42.3% of the cases it was felt that the headaches were not related to MAGNEVIST® Injection. Injection site coldness/localized coldness is the second most common adverse experience at 4.8%. Nausea occurs in 3.2% of the patients.

Localized pain, vomiting, paresthesia, dizziness and localized warmth occur in less than 2% of the patients.

The following additional adverse events occur in less than 1% of the patients:

Body as a Whole: Injection site symptoms, namely, pain, warmth, burning; localized burning sensation, substernal chest pain, fever, weakness, generalized coldness, localized edema, tiredness, chest tightness, regional lymphangitis, anaphylactoid reactions (characterized by cardiovascular, respiratory and cutaneous symptoms).

Cardiovascular: Hypotension, vasodilation, pallor, non-specific ECG changes, angina pectoris, phlebitis.

Digestive: Gastrointestinal distress, stomach pain, teeth pain, increased salivation.

Nervous System: Agitation, thirst, convulsions (including grand mal).

Respiratory System: Throat irritation, rhinorrhea, sneezing, dyspnea, wheezing, laryngismus, cough.

Skin: Rash, sweating, pruritus, urticaria (hives).

Special Senses: Tinnitus, conjunctivitis, visual field defect, taste abnormality, dry mouth, lacrimation disorder (tearing), eye irritation.

Laboratory: Transient elevation of serum transaminases.

The following other adverse events were reported. A causal relationship has neither been established nor refuted.

Body as a Whole: Back pain, pain, generalized warmth.

Cardiovascular: Hypertension, tachycardia, migraine, syncope, death related to myocardial infarction or other undetermined causes.

Digestive: Constipation, diarrhea.

Nervous System: Anxiety, anorexia, nystagmus, drowsiness, diplopia, stupor.

Skin: Facial edema, erythema multiforme, epidermal necrolysis.

Special Senses: Eye pain, ear pain.

Data from foreign studies did not reveal any additional adverse experiences.

OVERDOSAGE

The LD_{50} of intravenously administered gadopentetate dimeglumine injection in mice is 5-12.5 mmol/kg and in rats it is 10-15 mmol/kg. The LD_{50} of intravenously administered MAGNEVIST® Injection in dogs is greater than 6 mmol/kg.

Clinical consequences of overdose with MAGNEVIST® Injection have not been reported.

DOSAGE AND ADMINISTRATION

The recommended dosage of MAGNEVIST® Injection is 0.2 mL/kg (0.1 mmol/kg), administered intravenously, at a rate not to exceed 10 mL per minute. More rapid injection rates may be associated with nausea. The maximum total dose is 20 mL. Any unused portion must be discarded.

DOSAGE CHART

Body Weight (kg)	Dose in mL	Approx Duration of Injection in Seconds
10	2.0	20
20	4.0	30
30	6.0	40
40	8.0	50
50	10.0	60
60	12.0	70
70	14.0	80
80	16.0	95
90	18.0	110
100	20.0	120

To ensure complete injection of the contrast medium, the injection should be followed by a 5-mL normal saline flush. The imaging procedure should be completed within 1 hour of injection of MAGNEVIST® Injection.

Parenteral products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

For full prescribing information, see package insert.

Caution: Federal Law Prohibits Dispensing Without Prescription.

BERLEX IMAGING®

A 'Stress' Test for Memory Dysfunction

Electrophysiologic Manifestations of Early Alzheimer's Disease

Leyla deToledo-Morrell, PhD; Susan Evers; Thomas J. Hoeppner, PhD; Frank Morrell, MD, MSc; David C. Garron, PhD; Jacob H. Fox, MD

• Long-latency event-related potentials (P300) were assessed in patients wth early probable Alzheimer's disease (AD), age-matched controls, and young adults during a task that imposed various degrees of demand on memory. Although patients with AD did not differ from age-matched controls when one item had to be remembered, their P300 potential was dramatically reduced in amplitude or absent with increasing memory load. Aged controls did not differ from young adults on this mesuer. P300 latency, however, did not differentiate patients with AD. Thus, electrophysiological abnormalities detected in the context of mnemonic demand may provide a sensitive marker of the early stages of probable AD.

(*Arch Neurol.* 1991;48:605-609)

The detailed investigations of Sutton et al[1] and of Donchin and colleagues[2-8] have shown that the P300 component of long-latency, endogenous, event-related potentials (ERPs) is intimately related to information-processing activities in normal young adults. The so-called P300 consists of a positivity, most prominently recorded from posterior regions of the scalp, that peaks at approximately 300 milliseconds following stimulus onset. With complex stimuli, the peak may occur later. In general, the above-cited research has demonstrated that P300 latency is an index of the time required for the categorization of events and is quite independent of the time needed for response selection and execution processes. On the other hand, P300 amplitude was shown to depend on the amount of information-processing activity evoked by a stimulus and to be especially sensitive to alterations in the subject's expectancy of an event.[9]

The P300 component of ERPs has been extensively used to study age-related[10-15] and disease-induced[14,16-20] alterations in cognitive function. In recent years, however, there has been some disappointment in the utility of the P300 as a diagnostic tool in clinical settings. One reason for this disappointment may be that most clinical studies have relied on the auditory oddball paradigm as the task to elicit ERPs and a delay in P300 latency as the crucial measure for diagnosing alterations in cognitive function and dementia. In the auditory oddball paradigm, two tones are presented with different probabilities and the subject has to count (or make a motor response to) the infrequently occurring stimulus. However, evidence indicates that (1) increases in P300 latency occur as a function of aging per se in nondemented adults,[11-13,15] and (2) an increase in P300 latency is not a very sensitive index of memory dysfunction during the *very early* stages of dementia[20,21] when a sensitive diagnostic tool would be most useful to the clinician. For example, in the Patterson et al[21] study, which employed the auditory oddball paradigm, only 13% of demented patients could be correctly classified on the basis of P300 latency. Most important, however, is the fact that delays in P300 latency have been observed in nondementing disorders such as depression and schizophrenia as well.[19]

Recently, reports from a number of laboratories, including ours, have indicated that the utility of the P300 for diagnosing specific types of memory disorders can be much improved if ERPs are recorded in the context of tasks that impose some demand or "stress" on memory function.[22-26] These studies, which showed that the P300 is much reduced in amplitude (or not present at all) during tasks with a strong mnemonic component in patients with memory disorders, underscore the importance of the behavioral tasks employed in the clinic to elicit electrophysiologic abnormalities in different patient populations. Given that P300 amplitude has been shown to be directly related to the degree of recall in young subjects,[6,7] it makes sense that this factor, rather than P300 latency, might provide a more sensitive marker of memory dysfunction.

We now report that alterations in P300 amplitude recorded during a task that imposes different degrees of demand or stress on mnemonic function provide a sensitive electrophysiologic marker of the very early stages of probable Alzheimer's disease (AD). In our hands, alterations in P300 latency did not differentiate patients with AD from age-matched controls.

SUBJECTS AND METHODS

The data reported herein were obtained from six patients with presumed early AD ranging in age from 67 to 76 years (mean age, 72 years), seven age-matched controls ranging in age from 65 to 76 years (mean age, 71 years), and 11 young adults ranging in age from 22 to 38 years (mean age, 27 years). The patients with AD consisted of four right-handed women and two right-handed men, recruited through the Rush Alzheimer's Disease Center (Chicago, Ill) from among those who met the National Institute of Neurological Disorders and Stroke/Alzheimer's Disease and Related Disorders Association criteria for probable AD.[27] They had dementia documented by clinical and psychometric examination, and they had deficits in at least two areas of cognition with the *major* deficit being mnemonic in nature. Only patients with mild dementia, as defined by a Mini Mental State[28] score of 20 or greater, were included in this study. The Mini Mental State scores of our patients ranged from 24 (only one patient) to 21, with a mean of 22.5. Dementia and memory scores for individual patients with AD are presented in the Table.[29] Patients who showed evidence of disturbed consciousness or evidence of other neurologic or systemic illness that can produce dementia, who had a history of alcohol/substance abuse, or who had a history of a major psychiatric disorder were excluded from the study.

The age-matched controls consisted of five right-handed women and two right-handed men who were recruited primarily from the Rush Medical Center Volunteer Office and from among spouses of patients with AD. They were all in good health and led active lives. The young adult subjects (five right-

handed men, one left-handed man, and five right-handed women) were mostly medical students, electroencephalography technicians, and junior faculty members.

If subjects normally wore corrective lenses, they were asked to keep them on during the test. Informed consent was obtained from all subjects according to the rules of the Human Investigation Committee of Rush Medical College.

Stimuli and Procedure

All aspects of experimental control and data collection were carried out with a computer system (Pearl System, PDP-11/40) designed and built at the Cognitive Psychophysiology Laboratory of the University of Illinois, Champaign. The ERPs were recorded during a modified Sternberg[30] memory scanning task. On a television monitor, subjects were shown a set of letters to be studied and remembered, memory set size varying from one to five letters. During the "study period," the letters remained on the screen for 60 seconds. After each study period for a given set size, single letters were presented one at a time for 700 milliseconds and subjects were asked to press one key with a given hand if the letter was from the memory set, and a second key with the other hand if it was any other letter of the alphabet. The hand used for each type of response was counterbalanced across subjects. Previously memorized letters (target) were presented with a probability of 24%. One hundred single-letter presentations or trials were used for each memory set size, the intertrial interval averaging 3500 milliseconds. The order of testing with each memory set size was counterbalanced, except that because of the patients with AD, testing was never started with a memory set size of five letters. Thus, as modified in our hands, the Sternberg task provides a measure of recent memory rather than immediate memory.

Recording and Quantification of the P300 Potential

Using the International 10-20 System,[31] silver chloride electrodes (Grass) were affixed with collodion at the following regions: P_z (midline parietal), F_z (midline frontal), P_3 (left parietal), P_4 (right parietal), A_1 (left ear lobe), A_2 (right ear lobe), and an additional cephalic location to be used as ground. For recording, P_z and F_z were referred to linked ears, P_3 and P_4 each to ipsilateral ear since, in this case, a linked ear reference would have been inadequate for detecting lateralized abnormalities. Eye movements were monitored by recording between two electrodes placed above and below the right eye. Trials contaminated by eye blinks were eliminated. Subjects were given extensive instructions to control their eye blinks while a stimulus was on the screen and to blink only between trials. Since most subjects, including patients with AD, complied with these instructions well, contamination by eye-movement artifact was not much of a problem in our experiments. For any given individual subject, no more than six trials were ever eliminated.

Electrode impedance was kept equal to or below 3 kΩ. Bioelectric activity was amplified using amplifiers (Grass model 7P511 with filter settings between 0.1 and 100 Hz) and was digitized at the rate of 200 samples per second for 100 milliseconds prior to stimulus onset (which served as baseline) and for 900 milliseconds following stimulus onset. Single trial data were stored on magnetic tape for later off-line analyses. P300 amplitude and latency were automatically calculated by the computer. P300 amplitude was defined as the peak positivity occurring between 250 and 750 milliseconds following stimulus onset and was measured from baseline. P300 latency was defined as the time from stimulus onset to the peak positivity.

Dementia and Memory Scores for Patients With Probable Alzheimer's Disease

Patient No./Age, y/Sex	Folstein Mini Mental Score (Maximum = 30)	Mattis Dementia Rating Scale Scores	
		Total (Maximum = 144)	Memory Subscale (Maximum = 25)
1/73/M	21	123	12*
2/70/M	23	126	18*
3/74/F	21†	124	11*
4/76/F	23	118*	14*
5/67/F	23	119*	12*
6/74/F	24	132	16*

*Refers to scores on the Mattis[29] Dementia Rating Scale that are in the impaired range defined as 2 SDs below the mean.

†Average of two scores obtained close to the time of electrophysiologic testing.

Statistical Analyses

Group differences for each type of measure collected (such as P300 latency or amplitude, reaction time, and choice accuracy) were assessed by separate analyses of variance with ϵ correction for nonsphericity.[32] Further comparisons between two means consisted of two-tailed t tests for independent samples with probabilities corrected for the number of tests performed. A significance level of P less than .05 was set for all tests.

RESULTS

Electrophysiologic data described herein are based on P300 potentials recorded from midline parietal regions (P_z), since this report is not concerned with hemispheric asymmetries. Hemispheric differences in ERPs elicited during hemisphere-specific tasks are described elsewhere.[33]

Averaged ERPs for individual subjects elicited by target letters are presented in Fig 1. The top part of Fig 1 shows ERPs obtained from a typical elderly control subject when memory set sizes of one or five letters were used. Figure 1, center and bottom, provides a comparison of ERPs recorded from two patients with probable AD under the same conditions. Note that patients with AD had a well-formed P300 that was comparable to that of age-matched controls when a memory set size of one letter was used. With a memory set size of five letters, however, the P300 potential was absent or dramatically reduced in amplitude in the same patients. This effect was seen in all six patients with AD studied. A comparison of P300 amplitude (Fig 2) in patients with AD and age-matched controls (analysis of variance) showed a significant group difference ($P<.001$) as well as a memory load effect ($P<.001$). Further comparisons revealed that patients with AD did not differ from age-matched controls when one letter had to be remembered, but they showed significantly reduced P300 amplitudes with memory loads of two letters or more. There was no age effect per se on P300 amplitude in that aged controls did not differ from young adults.

In marked contrast to the amplitude measure, patients with AD did not differ from age-matched controls in P300 latency (Fig 3), but both showed significantly delayed potentials compared with young adults ($P<.005$ for the age effect). It could be argued that the latency measure for trial blocks requiring memory loads of four or five letters was not too accurate for patients with AD since it was difficult to detect a peak. However, even with a memory load of one or two items, when the P300 potential was well formed in patients with AD, its latency was comparable to that of age-matched controls. The age-related increase in P300 latency found in our study, which approximates 1.5 ms/y, is comparable to that reported in the literature.[11-13,15]

In our experiment, in addition to ERPs, two behavioral measures, namely reaction time and choice accuracy, were recorded. With respect to reaction time (Fig 4), patients with AD responded just as rapidly as age-matched controls to target letters when a memory load of one letter was required. This result indicates that patients with AD did not have any motor dysfunction. However, they were much slower in responding than age-matched controls

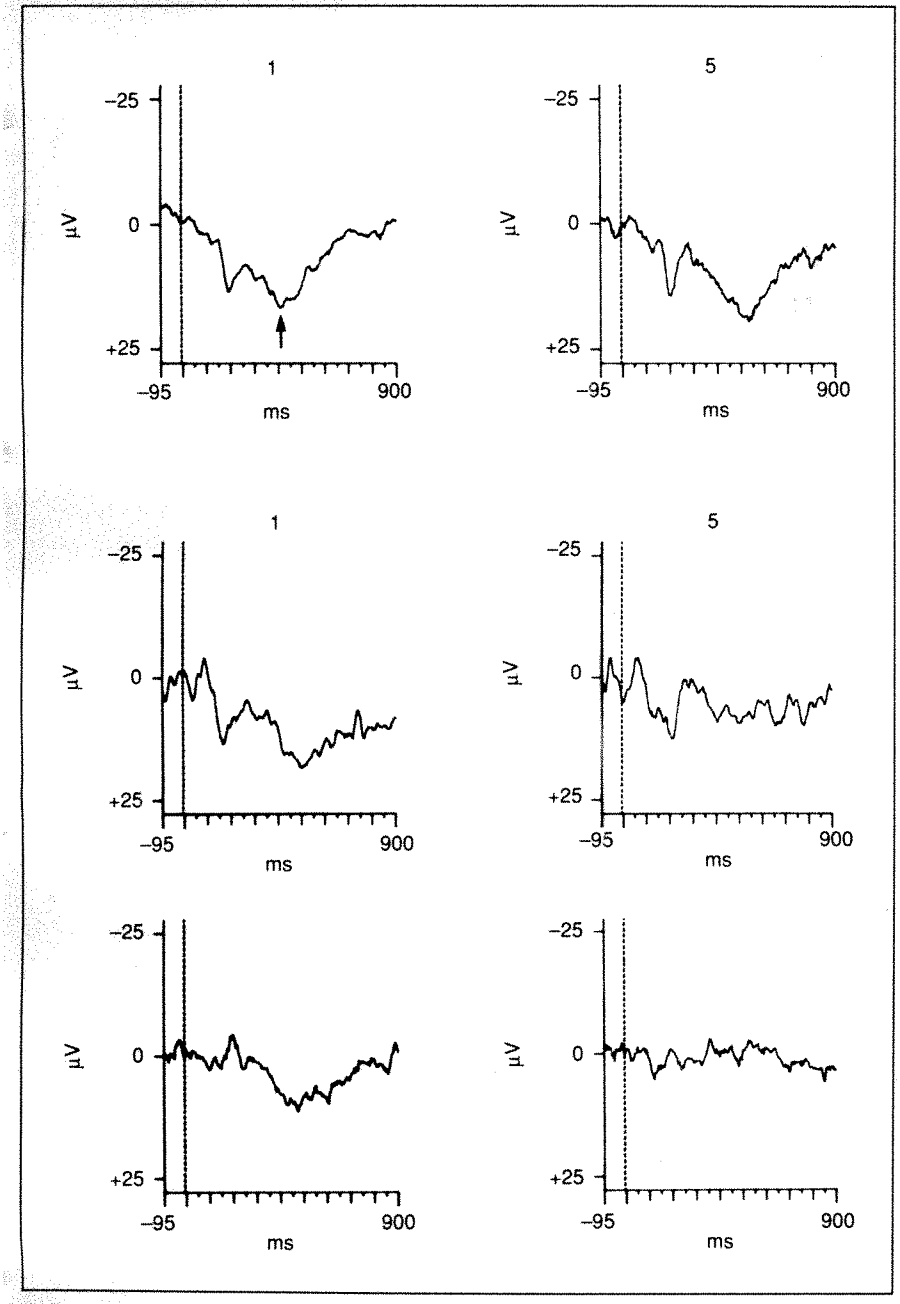

Fig 1.—Averaged event-related potentials (ERPs) elicited by target letters (N = 24). Top, ERPs obtained from an elderly control subject when memory set sizes of one (left) or five (right) letters were used. Center and bottom panels provide a comparison of ERPs obtained from two patients with Alzheimer's disease under the same conditions. Downward deflection indicates positivity at the scalp electrode. The arrow in top left shows the peak of the P300. Note, in particular, that the positive peak at about 200 milliseconds after stimulus onset in the control and the upper of the two patient records is *not* a P300.

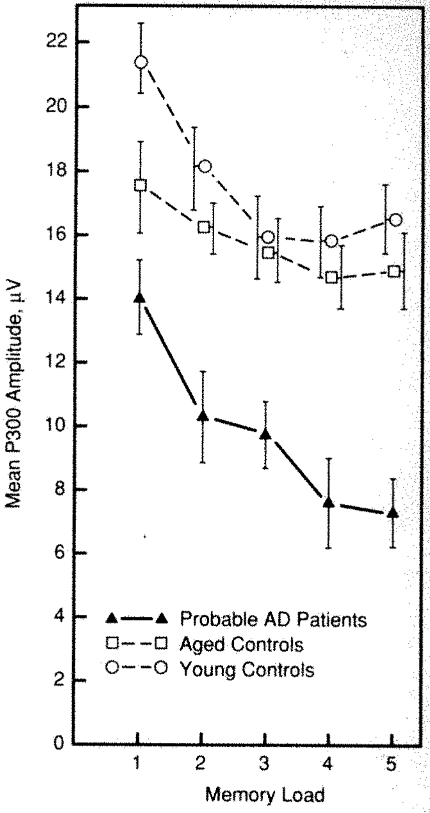

Fig 2.—Mean P300 amplitude to target letters as a function of memory set size in patients with probable Alzheimer's disease (AD), age-matched controls, and young adults. Vertical bars indicate the SEM.

with increasing memory load. An analysis of variance comparing patients with AD with age-matched controls revealed a significant group × memory load interaction ($P<.01$). Further comparisons indicated a difference in reaction time between the two groups with a memory load of five letters. This large increase in reaction time with increasing memory load in patients with AD compared with age-matched controls is indicative of a longer search of temporarily stored information and provides a quantitative behavioral measure of memory dysfunction.

The other behavioral measure, choice accuracy to target letters (Fig 5), showed results similar to reaction time, although in this case, differences between patients with probable AD and elderly controls were less dramatic. Even though an analysis of variance on choice accuracy to target letters revealed a significant group × memory load interaction ($P<.02$), indicating that patients were less accurate with increasing memory load, individual comparisons for each load did not reach significance when probabilities were corrected for the number of *t* tests performed.

COMMENT

Compared with aged individuals, patients with probable AD showed a marked diminution in the amplitude of the P300 component of ERPs recorded during a modified Sternberg memory scanning task *only* when increasing degrees of demand or stress were imposed on mnemonic function. As in the case of a "cardiac stress test," the term *stress* is used herein to refer to a load or demand on the particular system involved. Although patients with AD did not differ from age-matched controls when one item had to be remembered, their P300 potential was significantly reduced in amplitude with increasing memory load. Aged controls did not differ from young adults on this measure. P300 latency, on the other hand, did not differ-

entiate patients with AD from age-matched controls, although both showed delayed potentials compared with young adults. The lack of a significant increase in P300 latency in patients with AD compared with aged controls in our study is not surprising given that patients with AD consisted of individuals with mild dementia who were in the early stages of the disease. As indicated in the introduction, Polich et al[20] have demonstrated that an increase in P300 latency is not a sensitive index of memory dysfunction in the early stages of dementing illnesses.

In the present study, the loss or diminution of the P300 potential under conditions of mnemonic stress seemed to provide a more sensitive marker of the dysfunction in the patient population than either behavioral measure recorded during the task. More specifically, the patients with probable AD differed significantly from age-matched controls in P300 amplitude even with a minimal memory load of two letters, while a much greater load was needed before differences in behavioral measures could be detected.

The excessive diminution of P300 amplitude with increasing memory load in the patient population does not seem to be a function of a marked reduction in accuracy. For example, the patient with probable AD whose ERPs are plotted in the bottom tracing of Fig 1 was performing at 80% accuracy with a memory load of five letters, and yet, among the patients with AD, his P300 showed the greatest reduction in amplitude with increasing memory load.

We also reexamined ERP data for some of the patients with probable AD by averaging trials on which they made accurate choices separately from error trials. The ERP data for correct "target" trials were very similar to those described above for all target trials. In addition, we recently tested a patient with dementia due to vascular causes whose choice accuracy was much worse than that of any of the patients with AD included in this study; his P300 potentials, however, were very comparable to those of age-matched controls even with a memory load of five letters. This case provides an excellent example of the dissociation between behavioral (as indicated by choice accuracy) and electrophysiologic findings.

It should also be pointed out that although our task was visual in nature, the results we report cannot be accounted for by possible abnormalities in the peripheral visual system in patients with probable AD.[34] First of all, such peripheral visual system abnormalities would be expected to affect latency measures far more than amplitude measures. Second, in our experiment, following the study period for a given memory set size, all testing was carried out with single-letter presentations. The only variable that differed from trial block to trial block was the number of letters a subject had to remember. Since the task was visual in nature under all conditions, possible peripheral visual abnormalities would have played an equal role in the case of testing with a memory set size of one letter, as well as with four or five letters. Yet, as indicated above, patients with probable AD did not differ from age-matched controls in P300 amplitude when a memory set size of one letter was required.

The occurrence or nonoccurrence of a P300 potential in an individual is not, in itself, a useful marker of memory dysfunction or of a disease process. Lack of this so-called cognitive ERP may be observed in various populations and may result from failure to cooperate with the test, inattention, etc. However, when the P300 is well formed with a minimal memory load and comparable in amplitude to that of controls, but is markedly diminished in amplitude or lost as the memory load increases, patients, in a sense, provide their own controls. Used in the manner described in this article, the modified Sternberg paradigm provides a "stress test" of the integrity of the neural circuitry on which the registration of new experience depends. That circuitry is likely to include the hippocampal formation.

The hippocampal formation is a structure critically involved in the registration of many forms of newly acquired information.[35,36] There is now a substantial body of work indicating that the P300 potential may be generated in or near the hippocampus,[37-40] although it is still not certain that the scalp-recorded P300 has the same origin as that event of similar latency derived from indwelling electrodes in limbic cortex. Nevertheless, it seems likely that the P300 generated in the context of a recent memory task, which is probably dependent on the hippocampus for its accurate performance, reflects the action of hippocampal neurons. Although the correctness of this assumption is not crucial for our conclusion, it is of interest that a direct relationship between hippocampal cell loss or pathology and P300 abnormalities has been found in two recent studies of epileptic patients.[39,41]

Hippocampal pathology or disconnection has been amply demonstrated in AD and is thought to be responsible for the memory impairment associated with the early stages of the disorder.[42-46] We suggest that the recording of ERPs in the context of the Sternberg paradigm, as modified in our hands, may prove to be especially sensitive for the detection of hippocampal abnormalities. Since disturbance in the acquisition of new information is one of the hallmarks of probable AD, the P300 test described herein may provide a sensitive, noninvasive, diagnostic tool or marker during the very early stages of the disease.

This study was supported in part by grant AGO3151 from the National Institute on Aging, Bethesda, Md, and by the Rush Alzheimer's Disease Center.

Marija Norusis, PhD, Department of Preventive Medicine, Rush Medical College, gave advice and helped with the statistical analyses reported herein.

Cafergot®

(ergotamine tartrate and caffeine) tablets, USP
(ergotamine tartrate and caffeine) suppositories, USP

DESCRIPTION

Cafergot® (ergotamine tartrate and caffeine) Tablet

ergotamine tartrate USP .... 1 mg
caffeine USP .... 100 mg

Inactive Ingredients: acacia, carnauba wax, lactose, methylparaben, povidone, propylparaben, sodium benzoate, sorbitol, starch, stearic acid, sucrose, synthetic black ferric oxide, synthetic red ferric oxide, synthetic yellow ferric oxide, talc, tartaric acid, and titanium dioxide.

Cafergot® (ergotamine tartrate and caffeine) Suppository

ergotamine tartrate USP .... 2 mg
caffeine USP .... 100 mg

Inactive Ingredients: cocoa butter NF and tartaric acid NF.

Cafergot® (ergotamine tartrate and caffeine) suppositories are *sealed* in foil to afford protection from cocoa butter leakage. If an unavoidable period of exposure to heat softens the suppository, it should be chilled in ice-cold water to solidify it before removing the foil.

ACTIONS: Ergotamine is an alpha adrenergic blocking agent with a direct stimulating effect on the smooth muscle of peripheral and cranial blood vessels and produces depression of central vasomotor centers. The compound also has the properties of serotonin antagonism. In comparison to hydrogenated ergotamine, the adrenergic blocking actions are less pronounced and vasoconstrictive actions are greater.

Caffeine, also a cranial vasoconstrictor, is added to further enhance the vasoconstrictive effect without the necessity of increasing ergotamine dosage.

Many migraine patients experience excessive nausea and vomiting during attacks, making it impossible for them to retain any oral medication. In such cases, therefore, the only practical means of medication is through the rectal route where medication may reach the cranial vessels directly, evading the splanchnic vasculature and the liver.

INDICATIONS

Cafergot® (ergotamine tartrate and caffeine)

Indicated as therapy to abort or prevent vascular headache, e.g., migraine, migraine variants or so-called "histaminic cephalalgia".

CONTRAINDICATIONS: Peripheral vascular disease, coronary heart disease, hypertension, impaired hepatic or renal function, sepsis and pregnancy.

Hypersensitivity to any of the components.

PRECAUTIONS: Although signs and symptoms of ergotism rarely develop even after long term intermittent use of the orally or rectally administered drugs, care should be exercised to remain within the limits of recommended dosage.

Ergotism is manifested by intense arterial vasoconstriction, producing signs and symptoms of peripheral vascular ischemia. Ergotamine induces vasoconstriction by a direct action on vascular smooth muscle. In chronic intoxication with ergot derivatives, headache, intermittent claudication, muscle pains, numbness, coldness and pallor of the digits may occur. If the condition is allowed to progress untreated, gangrene can result.

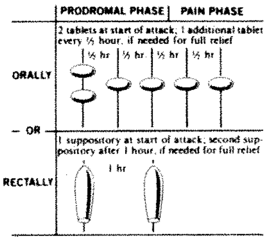
While most cases of ergotism associated with ergotamine treatment result from frank overdosage, some cases have involved apparent hypersensitivity. There are few reports of ergotism among patients taking doses within the recommended limits or for brief periods of time. In rare instances, patients, particularly those who have used the medication indiscriminately over long periods of time, may display withdrawal symptoms consisting of rebound headache upon discontinuation of the drug.

There have been reports of drug abuse and psychological dependence in patients on Cafergot® (ergotamine tartrate and caffeine) therapy. Due to the chronicity of vascular headaches, it is imperative that patients be advised not to exceed recommended dosages with long-term use to avoid ergotism.

ADVERSE REACTIONS: Vasoconstrictive complications, at times of a serious nature, may occur. These include pulselessness, weakness, muscle pains and paresthesias of the extremities and precordial distress and pain. Although these effects occur most commonly with long-term therapy at relatively high doses, they have also been reported with short-term or normal doses. Other adverse effects include transient tachycardia or bradycardia, nausea, vomiting, localized edema and itching.

DOSAGE AND ADMINISTRATION

Procedure: For the best results, dosage should start at the first sign of an attack.



PRODROMAL PHASE
PAIN PHASE
ORALLY
2 tablets at start of attack; 1 additional tablet every ½ hour, if needed for full relief
½ hr
½ hr
½ hr
½ hr
— OR —
RECTALLY
1 suppository at start of attack; second suppository after 1 hour, if needed for full relief
1 hr

Early Administration Gives Maximum Effectiveness

MAXIMUM ADULT DOSAGE

Orally: Total dose for any one attack should not exceed 6 tablets.

Rectally: Two suppositories is the maximum dose for an individual attack.

Total weekly dosage should not exceed 10 tablets or 5 suppositories.

In carefully selected patients, with due consideration of maximum dosage recommendations, administration of the drug at bedtime may be an appropriate short-term preventive measure.

OVERDOSAGE: The toxic effects of an acute overdosage of Cafergot® (ergotamine tartrate and caffeine) are due primarily to the ergotamine component. The amount of caffeine is such that its toxic effects will be overshadowed by those of ergotamine. Symptoms include vomiting, numbness, tingling, pain and cyanosis of the extremities associated with diminished or absent peripheral pulses; hypertension or hypotension; drowsiness, stupor, coma, convulsions and shock. A case has been reported of reversible bilateral papillitis with ring scotomata in a patient who received five times the recommended daily adult dose over a period of 14 days.

Treatment consists of removal of the offending drug by induction of emesis, gastric lavage, and catharsis. Maintenance of adequate pulmonary ventilation, correction of hypotension, and control of convulsions are important considerations. Treatment of peripheral vasospasm should consist of warmth, but not heat, and protection of the ischemic limbs. Vasodilators may be used with benefit but caution must be exercised to avoid aggravating an already existent hypotension.

HOW SUPPLIED

Cafergot® (ergotamine tartrate and caffeine) Tablets

Shell pink colored, sugar coated, imprinted "CAFERGOT" on one side, "⚠" on other side. Bottles of 250, NDC 0078-0034-28, and cartons of three SigPak® (dispensing unit) packages, each containing 30 tablets in individual blisters, NDC 0078-0034-42.

Cafergot® (ergotamine tartrate and caffeine) Suppositories

Sealed in fuchsia-colored aluminum foil, imprinted "⚠ CAFERGOT® SUPPOSITORY 78-33 SANDOZ". Boxes of 12, NDC 0078-0033-02.

[DECEMBER 1, 1990 CAF-Z26]

Retrospective Postmortem Dementia Assessment

Validation of a New Clinical Interview to Assist Neuropathologic Study

Paula B. Davis, MD; Heidi White, MD; Joseph L. Price, PhD; Daniel McKeel, MD; Lee N. Robins, PhD

• Neuropathologic studies of dementia and normal aging suffer from a lack of individuals examined for the presence and severity of dementia before death. To increase clinical information in such cases, a retrospective collateral interview was developed. Thirty-nine individuals were studied; 27 had autopsies. In all cases, the autopsy confirmed the Retrospective Collateral Dementia Interview (RCDI) diagnosis of the presence or absence of dementia; the RCDI had a sensitivity of 88% and a specificity of 80% for specifically detecting probable Alzheimer's disease. Agreement between the RCDI and premortem diagnosis was 96%; between RCDI and medical records, 100%. Agreement between RCDI staging of dementia severity and the last assessment of the living subject was 70%; between the RCDI and a brief staging at death, 86%. This validation confirms the value of postmortem interviews with close informants to assess dementia presence and severity.

(*Arch Neurol.* 1991;48:613-617)

Neuropathologic findings of appropriate numbers and distribution of neurofibrillary tangles and senile plaques[1] remain the gold standard for the diagnosis of senile dementia of the Alzheimer type (SDAT). To understand the spectrum of disease, brain tissue from persons of a broad range of ages and disease severity, including nondemented persons, is highly desirable. Clinicopathologic studies of SDAT and normal aging, however, are plagued by a lack of individuals who are examined for the clinical presence and severity of dementia before death. Even in longitudinal studies of healthy aging and senile dementia, few individuals come to autopsy at a young age or in very mild or moderate stages of dementia. Further, as dementia progresses, it is more difficult for subjects in longitudinal studies to be examined for revised staging of their dementia severity.

In the living subject, the most common source of information about a cognitively impaired person is an interview with an informant, someone who is aware of the person's cognitive and functional abilities or impairment.[2,3] The same resource is often available after death. The psychiatric literature supports the value of such collateral-source information after death in the case of suicide.[4-6] A carefully constructed instrument to interview a knowledgeable collateral source has been shown to be useful and reliable.[4]

Kukull and Larson[7] used a mailed questionnaire to elicit collateral-source information after death to establish a diagnosis of primary degenerative dementia. While highly sensitive, the questionnaire had low specificity. We have devised a collateral-source interview to be used specifically after death. This article presents our study of this interview's validity in making a diagnosis of the presence or absence of dementia, a differential diagnosis of SDAT, and a staging of dementia severity.

PATIENTS AND METHODS

The Retrospective Collateral Dementia Interview (RCDI) is a retrospective, structured telephone interview, conducted with a knowledgeable collateral source, that takes approximately 40 minutes. It was adapted from the Informant Interview given in the Adult Lifestyle and Function Study (1986 and 1987; L. N. Robins, MD, R. F. Fischbach, MD, and P.B.D.), a follow-up study conducted in St Louis, Mo, of elderly participants in the Epidemiologic Catchment Area Study (1981 and 1982) conducted in five sites (including St Louis) by the National Institute of Mental Health, Bethesda, Md.[8,9] The interview includes questions about the relationship between the collateral source and the subject (eg, family or friend and frequency of contact), the circumstances of the subject's death, basic sociodemographic information, and family history of memory disorders. It further asks about aphasia (problems with speech and writing); medical conditions, especially those pertinent to memory (eg, depression, Parkinson's disease, stroke, and seizure disorder); and other factors that can affect cognition (eg, hearing and vision disorders and alcohol and medication use). It also queries the expression of the dementing illness, such as behavioral problems and changes in personality and judgment.

Regarding memory and orientation, questions are posed to elicit the onset, course, and nature of the problems, ie, recent and/or remote memory (by specific items) and orientation to person, place, and time (by specific items). The RCDI includes questions operationalizing the Blessed Dementia Scale items[3] and the Activities of Daily Living scale of Katz et al.[10] These questions are not presented in order as a single set but, rather, are distributed throughout the interview. Thus,

the clinician is unaware of the subject's score on the Blessed Dementia Scale during assessment and assignment of severity staging. The RCDI was given by either a physician trained and experienced in dementia evaluation or a senior medical student trained in its administration. (The interview was conducted in one case as a written questionnaire at the request of the collateral source.) Interviews conducted by the student were reviewed with the physician, who assigned a diagnosis and severity rating. The interviewer was blinded to all other information regarding the patient when giving and scoring the interview.

Information obtained in the interview allowed the clinician to assign diagnoses in accordance with the Work Group Criteria of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS), Bethesda, Md, and the Alzheimer's Disease and Related Disorders Association (ADRDA), Chicago, Ill, for probable Alzheimer's disease.[11] Briefly, SDAT was diagnosed when dementia, consisting of memory loss and impairment of other cognitive abilities, began insidiously and followed a gradually progressive course for 6 months or longer in the absence of other disorders that could account for these changes. Possible SDAT was diagnosed when the above criteria were fulfilled, but either the course was atypical or another (or more than one other) contributing disorder was also present. To compare with neuropathologic findings at autopsy, the contributing disorders considered were vascular dementia and Parkinson's disease.[1,12] Subjects who had no intellectual dysfunction were considered cognitively normal.

Diagnoses made solely from the RCDI were compared with (1) diagnoses given by a physician examining the live subject at the Washington University Alzheimer's Disease Research Center (ADRC), St Louis, Mo, using criteria[13] developed earlier but essentially identical to that of NINCDS-ADRDA; (2) medical records; and (3) neuropathologic findings from autopsy. All neuropathologic autopsies were reviewed by a single neuropathologist. Autopsy cases were divided into the following three groups: cognitively normal, pure Alzheimer's disease (AD) (according to Khachaturian's criteria[1]), or other dementias.

Dementia severity was scored using the Clinical Dementia Rating (CDR), a rating scale of the subject's overall dementia severity.[14,15] Six areas of function (memory, orientation, judgment and problem solving, community affairs, home and hobbies, and personal care) are assessed, and an overall rating is assigned according to established rules. The CDR scores are as follows: CDR 0, normal; CDR 0.5, questionable (or very mild) dementia; CDR 1, mild dementia; CDR 2, moderate dementia; and CDR 3, severe dementia. Severity ratings from the RCDI alone were compared with the following: (1) the CDR given at the last assessment of the living subject and (2) the CDR obtained from a brief (10- to 15-minute), semistructured, telephone ADRC Expiration Interview conducted at the time of the subject's death.

The rating of dementia severity from the full RCDI (the CDR) was also compared with the summary score of the Blessed Dementia Scale[3] items embedded within the RCDI. The full Blessed Dementia Scale is scored with a range of 0 (normal) to 28 (severely impaired); while all items were included in the RCDI, the scores of 0.5 were unavailable for four items (could only score 0 or 1); and scores of 1 were unavailable for one item (could only score 0, 2, or 3). The Blessed Dementia Scale consists of the following two subtests: the Blessed Dementia Scale–Cognitive, scored 0 (normal) to 17 (severely impaired); and the Blessed Dementia Scale–Personality, Interests, and Drives, ranging from 0 (normal) to 11 (severely impaired). In a previous study of living subjects in the Memory and Aging Project and the ADRC of Washington University, subjects' scores on the Blessed Dementia Scale and Blessed Dementia Scale–Cognitive were highly correlated with their CDR scores (0.79 and 0.84, respectively).[16]

After explaining the nature of the study and obtaining consent, collateral sources of the following subjects participated: 23 ADRC subjects who died from July 1986 through January 1989, four persons who donated their bodies to the Washington University School of Medicine, and 12 persons from the general autopsy service. Collateral sources were spouses (17 individuals), adult daughters (14 individuals), adult sons (three individuals), siblings (three individuals), daughter-in-law (one individual), and a nonrelative (one individual). The mean time from death until the interview was conducted was 8 months (range, 2 to 21 months). Demographic characteristics of the subjects studied are presented in Table 1.

Brains were available from 18 of 23 ADRC subjects, two of four participants in the body-donation program, and seven of 12 individuals who underwent general autopsies. All 23 ADRC subjects had a diagnosis and severity staging obtained in life; 21 of these 23 subjects had a restaging of dementia severity from the brief ADRC Expiration Interview at death. Medical records were available in all but one case; that person had a neuropathologic autopsy, however.

RESULTS

Diagnosing Dementia

Six subjects diagnosed by the RCDI as cognitively normal had autopsies, and all were confirmed to be cognitively normal (Tables 2 and 3). Twenty-one subjects diagnosed by the RCDI as having SDAT alone or with another dementing illness underwent autopsies, and all were confirmed to have SDAT. Further, 15 of these subjects were considered to have probable SDAT from the interview—14 of these subjects were confirmed as pure AD neuropathologically, and the last had mixed de-

*Diagnoses from Retrospective Collateral Dementia Interview (RCDI): CN indicates cognitively normal; AD, probable Alzheimer's disease; PAD, possible Alzheimer's disease; and PD, Parkinson's disease.

†Diagnoses from neuropathologic autopsy; CN indicates cognitively normal; AD, pure Alzheimer's disease; and other, AD and other illness(es).

‡CDR indicates Clinical Dementia Rating; CDR scores as follows: 0, no dementia; 0.5, questionable dementia; 1, mild dementia; 2, moderate dementia; and 3, severe dementia.

§No premortem assessment available; medical records confirmed cognitively normal for cases 29 through 34 and confirmed possible AD for case 38.

mentia, vascular and AD, at autopsy. Of six cases diagnosed by the RCDI as possible SDAT, four were confirmed as atypical AD or as having another dementing disorder in addition to AD. The other two cases had only AD at autopsy. Thus, the RCDI had 100% sensitivity and specificity for detecting the presence or absence of dementia and had 88% sensitivity and 80% specificity for detecting pure AD from mixed dementias that included AD.

We next compared diagnoses from the RCDI with those made when the subject was alive (23 subjects). Three subjects were diagnosed as cognitively normal both by the RCDI and the last premortem clinical assessment. One subject was diagnosed as having probable AD by the RCDI; she was considered cognitively normal at the last clinical assessment. Of the other 15 subjects diagnosed by the RCDI as having probable SDAT, premortem assessment agreed with the RCDI assessment in all cases. Three subjects were diagnosed by the RCDI as having possible SDAT. Two of these three individuals had been considered to have possible AD at their last premortem clinical assessment and one had probable AD. One subject had vascular dementia by both the RCDI and the clinical assessment.

Diagnoses from the RCDI were confirmed by review of medical records, given their limitations.[17] Thus, by comparison with all available standards the RCDI always detected dementia if present and always detected normal cognitive function (case 7 had been considered normal at the last clinical assessment, was diagnosed as probable AD by the RCDI, and was confirmed as pure AD by autopsy). The RCDI misclassified two cases of AD as possible AD, and one case of mixed dementia as pure AD.

Determining the Severity of Dementia

The RCDI also performed well at staging dementia severity. There was 70% agreement between the CDR from the RCDI and the CDR from the last premortem clinical assessment, and 86% agreement between the RCDI-generated CDR and the ADRC Expiration Interview CDR (Table 3). Increasing the time from the last clinical assessment to death had little effect on the agreement of the retrospective interview with premortem staging of severity (Table 4); neither did more elapsed time lessen agreement between the RCDI and the ADRC Expiration Interview. Differences between the retrospective interview staging and premortem staging by CDR category were noted, with less agreement seen for the CDR scores of 0.5, 1, and 2 than for the CDR scores of 0 or 3. The three cases showing discrepancies in staging between the RCDI and the ADRC Expiration Interview all were rated as more severely affected by the RCDI. Older subjects were no more difficult to assess than were younger subjects, although most cases fell into one age category (75 to 84 years).

We also compared the global CDR derived from the RCDI with the rating from the embedded Blessed Dementia Scale[3] items. Using the full Blessed Dementia Scale or the Blessed Dementia Scale–Cognitive, good correlation between the briefer tests and the global CDR was established (0.71 and 0.74, respectively).

COMMENT

A structured, retrospective telephone interview with a knowledgeable collateral source conducted after a subject's death provides both a valid identification of dementia and a diagnosis of SDAT. These findings make the retro-

spective telephone interview a valuable additional source of clinical information for neuropathologic studies of dementia and normal aging. An interview conducted by either an experienced dementia researcher or a well-trained interviewer, with subsequent review and assignment of the diagnosis by an experienced dementia researcher, yielded both the high sensitivity of Kukull and Larson's[7] mail questionnaire and high specificity. The appropriate classification of all cognitively normal subjects is an exciting finding, suggesting that the RCDI will be very useful in documenting normal cognitive function in subjects (young and old) not clinically assessed before death whose brains are available for neuropathologic study. Case 7, in which the RCDI and premortem assessment disagreed, involved a subject followed up prospectively for 7 years as a healthy control. At the second-to-last clinical assessment, the subject was rated as having questionable or very mild dementia (CDR, 0.5). However, the last assessment before death rated the subject cognitively normal (CDR, 0). The subject died 9 months after her last assessment and had the classic findings of AD on neuropathologic autopsy. The RCDI, which was conducted blinded to the above information, had rated the subject as having questionable or very mild dementia (CDR, 0.5). This suggests that this instrument will be helpful even in well-studied individuals who have not been examined recently.

All cases of dementia were identified, and the differential diagnosis of probable-vs-possible AD had high sensitivity and specificity. The ability of the interview to identify probable AD in samples with a lower AD prevalence, more representative of the population at large (50% to 60%), and the impact of the increased misclassification of mixed cases should be reassessed for its use in other settings. We were limited to very few cases of vascular dementia in our sample because of the recruitment pattern in the ADRC. In this study, case 21, misclassified by the RCDI as probable AD, had neuropathologic findings of Binswanger's type arteriosclerotic leukoencephalopathy[18] in addition to AD. The clinical expression of mixed Binswanger's type leukoencephalopathy and AD is difficult to differentiate from AD.[19] Case 26 was classified as possible AD (AD plus vascular) by the RCDI and pure AD by autopsy; case 27, classified as possible AD (AD plus Parkinson's disease) by the RCDI but which was pure AD by autopsy, was the case in which the informant refused a telephone interview but completed the interview as a mailed questionnnaire. Although the RCDI generally did well, its ability to differentiate pure AD from mixed cases may be enhanced by asking more questions about the extent of impact of reported strokes or Parkinson's disease and about the full course of dementia progression (not just onset and last year).

The RCDI can also detect clinical diagnoses, such as emphysema, alcoholism, cancer, depression, and medication effects, that are not standardly assessed by neuropathologic autopsy but that may contribute to the individual's clinical presentation and modify the course of the individual's disease. Further exploration of additional neuropathologic studies (eg, measuring the extent of involvement of Sommer's sector to assess hypoxia[20] or evaluating the degree of loss of cerebral white matter relative to cortex[21] and neuronal loss in the medial mamillary bodies to assess the chronic toxic effects of alcohol[22]) would be interesting to help sort out the pathophysiologic implications of these other disorders.

The retrospective interview also provides valid staging of dementia severity. We had expected cases with longer intervals between the premortem assessment and death to show greater disparity in severity staging because of progression of the disease. We actually found little effect, probably because most patients were either normal (CRD, 0) or severely demented (CDR, 3) at death.

We also expected to find greater differences in agreement between the retrospective interview staging and premortem staging for cases in CDR categories that were more likely to progress and harder to assess (eg, CDR score of 0.5).[23,24] While we did find less agreement for CDR scores of 0.5, 1, and 2 than for CDR scores of 0 and 3, our sample had few subjects in those categories. As interobserver agreement is greatest for the extremes of normal cognitive function and severe dementia, our sample is more likely to show good agreement because most subjects were in these categories. Whether or not some CDR categories are truly more difficult to assess by retrospective interview will require studying more patients with scores of 0.5, 1, and 2 at death.

We thought differences in accuracy of staging by the age of the subjects might be possible, ie, it might be even harder to discern questionable or mild dementia from "normal aging" in subjects older than 80 years of age than in those who were younger. Older subjects were no more difficult to assess than those who were younger; however, 21 of our 39 subjects were 75 to 84 years old when they died.

One instance of disagreement in staging between the RCDI and the ADRC Expiration Interview is the case discussed above with a CDR score of 0.5 by the RCDI, a diagnosis of probable AD, and confirmation of AD at autopsy, but that was rated cognitively normal (CDR, 0) by both the last premortem assessment and the ADRC Expiration Interview. A subject's CDR rating of 1 (mild dementia) by the ADRC Expiration Interview was rated 3 (severe dementia) by the RCDI; this individual had severe aphasia and hepatic carcinoma that we thought interfered with cognitive function.

Several factors may explain the incomplete agreement of staging from the retrospective interview with that from the ADRC Expiration Interview. When the CDR is assigned at death by ADRC, the 15-minute interview is conducted soon, usually within 1 to 7 days of death, and is usually conducted by the nurse rather than by the physician. As the telephone call also has other purposes than assigning a CDR, the call is usually placed to the spouse or whoever lived with the subject, even if that person was not the collateral source who accompanied the subject to premortem assessments. Open-ended questions provide some information about the immediate circumstances of death. Last, the interviewer knows the CDR assigned at the last clinical assessment.

The RCDI, by contrast, was usually performed after the period of acute grief (≥2 months). This introduces the possibility that the collateral source will have forgotten pertinent information. It was longer (about 40 minutes), fully structured, and done with the person who had served as the collateral source for premortem assessment. The interviewer was blinded to any information about the subject, including prior CDR score. The RCDI gathered more information about other medical illnesses (and medications), which often had also progressed since the last clinical assessment. These earlier minor problems had, at times, progressed to a degree such that we thought these problems also contributed to the subject's impaired cognition.

Comparing results from the RCDI with a well-studied index, the Blessed Dementia Scale and its subtests,[3] also confirmed its good performance in staging dementia severity.

A structured, retrospective interview with a knowledgeable collateral source properly diagnosed the presence or absence of SDAT and staged its severity. Use of the interview in larger samples with greater representation of some categories will be useful. Although this is a structured interview, for this study all interviews were conducted and diagnoses and/or staging were performed by trained researchers in dementia. We are currently modifying it slightly, as described above, to improve its ability to distinguish cases of pure AD from those of a mixed origin. As it appears most useful to use experienced researchers in dementia, incorporation of brief, unstructured segments may enhance diagnostic accuracy in unclear cases. Last, we are developing algorithms for automatic (computerized) scoring for diagnosis and staging, with further study of their validity and accuracy.

This investigation has been supported, in part, by training grant MH 17104 from the National Institute of Mental Health, Bethesda, Md, and by grants AG03991 and AG05681 from the National Institute on Aging, Bethesda, Md.

We are indebted to Leonard Berg, MD, Lawrence Coben, MD, Eugene Rubin, MD, PhD, and John C. Morris, MD, St Louis, Mo, for premortem clinical assessments; to Leonard Berg, MD, and John C. Morris, MD, for critical comments; to Ruth Fischbach, PhD, Boston, Mass, who coauthored the ALFI Informant Interview; to Lawrence T. McEvoy, MS, St Louis, for statistical data support; and to Connie Reisinger, St Louis, and Mary Gonzales, Pittsburgh, Pa, for secretarial support.

Copies of the interview are available on request.

Solving one puzzle of patient communications...

Medicolegal Forms with Legal Analysis

Medicolegal Forms with Legal Analysis is the ideal resource for assembling the legal pieces of your physician-patient relations. This **newly-revised** single volume contains virtually all the sample forms you need to develop customized medicolegal documentation for your medical practice.

Medicolegal Forms contains more than 80 sample forms developed by the AMA's Office of the General Counsel, along with discussions explaining the use and structure of the forms and case law citations.

Only *Medicolegal Forms with Legal Analysis* assembles this valuable information so conveniently for adaptation to individual practice situations.

Order your copy today; call toll-free **1-800-621-8335**

Neuropathologic and Neurochemical Correlates of Psychosis in Primary Dementia

George S. Zubenko, MD, PhD; John Moossy, MD; A. Julio Martinez, MD; Gutti Rao, MD;
Diana Claassen, MD; Jules Rosen, MD; Ursula Kopp

• Neuropathologic and neurochemical correlates of psychosis were determined using brain tissue from 27 autopsy-confirmed cases of Alzheimer's disease. The densities of senile plaques and neurofibrillary tangles were determined in the middle frontal and superior temporal cortex, the prosubiculum, and the entorhinal cortex of the hippocampus. The concentrations of norepinephrine, dopamine, and serotonin, the metabolites of these biogenic amines, and the specific activity of choline acetyltransferase were also determined in these four cortical regions as well as in the substantia nigra, thalamus, amygdala, and caudate nucleus. Psychosis was associated with significantly increased densities of senile plaques and neurofibrillary tangles in the prosubiculum and middle frontal cortex, respectively, with trends toward increased densities of these lesions in the other areas examined. This finding is consistent with the increased rate of cognitive decline that accompanies this behavioral disorder. Psychosis was also associated with the relative preservation of norepinephrine in the substantia nigra, with trends in this direction for five of the remaining seven brain regions examined, and a significant reduction of serotonin in the prosubiculum that was accompanied by trends toward reduced levels of serotonin and 5 hydroxyindoleacetic acid in the remaining regions. The profile of neuropathologic and neurochemical changes associated with psychosis is distinct from that previously reported for major depression in the context of primary dementia.

(*Arch Neurol.* 1991;48:619-624)

Psychosis, as defined by the presence of delusions or hallucinations, is a common behavioral complication of primary dementia in the elderly, and in Alzheimer's disease (AD) in particular. In fact, psychosis was present in the original case described by Alzheimer in 1907.[1] Estimates of the prevalence of psychosis in AD obtained from cross-sectional studies of clinically diagnosed patients evaluated in diverse clinical settings have ranged from 10% to 73%, with most estimates in the range of 28% to 38%.[2] In recent prospective, longitudinal studies, psychosis has been reported to emerge in approximately half of the patients with clinically diagnosed[3] or histologically confirmed[4] AD prior to death. Therefore, this behavioral syndrome constitutes an important source of comorbidity in patients with AD.

In addition to its relevance to clinical management, the development of psychosis in the context of AD has prognostic significance. Patients with psychosis exhibit a more rapid cognitive decline,[3-5] but not a higher rate of mortality,[3,4] than patients who do not develop this syndrome. These observations contrast with those for major depression, another common behavioral source of comorbidity in AD, which appears to be accompanied by an increased rate of mortality,[6,7] but not an increased rate of cognitive decline.[8]

The clinical and prognostic distinctions of psychosis and major depression provide evidence that supports the validity of these diagnoses in primary dementia, and also suggests that the neuropathologic and neurochemical determinants of these syndromes may not be identical. Chronic idiopathic psychoses that typically occur earlier in life have been reported to be accompanied by a selective decrease in blood flow[9-12] and decreased glucose metabolism[13-16] in the frontal cortex, and by cell loss and cytoarchitectural abnormalities in the neocortex and hippocampus.[17-22] These findings in such an etiologically heterogeneous group of patients suggests that they may also be relevant to psychoses of later onset, including those associated with neurodegenerative disorders. In contrast, major depression in primary dementia is associated with selective degeneration of aminergic nuclei in the brain stem,[6,7,23] but no increase in the density of senile plaques (SP) or neurofibrillary tangles (NFT) in the cerebral cortex.[6]

Based on these considerations, we performed a clinicopathologic study of psychosis using brain tissue from 27 patients who died with histologically confirmed AD. The densities of SP and NFT were quantified in four cortical regions, and the concentrations of biogenic amines and their metabolites, along with the specific activity of choline acetyltransferase, were determined in eight cortical and subcortical regions.

Accepted for publication December 13, 1990.

Reprint requests to the Geriatric Health Services, Western Psychiatric Institute and Clinic, Room E-1230, 3811 O'Hara St, Pittsburgh, PA 15213 (Dr Zubenko).

Morphologic and neurochemical correlates of psychosis are described and compared with those previously reported for major depression in 37 patients with primary dementia. In our previous study, 30 of 37 patients also met the histologic criteria for AD.[6]

SUBJECTS AND METHODS

Clinical Assessments and Subject Population

Subjects were referred from an ongoing longitudinal study of AD and related dementias. Written informed consent was provided by the patient's legal guardian (usually the next of kin) along with the patient's assent at the time of entry into the study. Written informed consent for autopsy was also provided by the legal guardian at the time of death. The 27 patients (13 males, 14 females) included in this study met consensus clinical criteria for probable or possible AD[24] and the *Diagnostic and Statistical Manual of Mental Disorders-III-Revised* criteria for primary degenerative dementia of the Alzheimer type,[25] as applied by board-certified neurologists and psychiatrists. The clinical and laboratory procedures used to operationalize these diagnostic criteria have been described in detail previously.[4,26-28] All 27 cases also met histopathologic criteria for AD, based on age-specific densities of SP and NFT.[29]

Psychiatric and Neurologic Assessments

Patients received complete psychiatric and neurologic examinations at the time of entry into the study, and these examinations were repeated annually until death. Each psychiatric examination included, but was not limited to, an assessment conducted according to the guidelines of the Initial Evaluation Form, a standardized instrument that specifies and defines the items to be covered, yet allows the clinician the flexibility to adjust to the order of items in the interview to probe for the information required.[30-32] The sections of the form include history of present illness; symptom inventory with specific items related to psychosis and to major depression; family, personal, and social history; physical health history and physical examination; diagnostic formulation; and disposition. Information is solicited from the patient, available caregivers, other informants, and documentary sources. This structured format was designed to cover all psychiatric disorders and has been validated for use in elderly psychiatric patients.[31]

The definition of psychosis in the *Diagnostic and Statistical Manual of Mental Disorders-III-Revised* requires "gross impairment in reality testing and the creation of a new reality."[25] According to this definition, delusions or hallucinations provide "direct evidence" of psychosis, but reasonable inference of a disturbance in reality testing from disorganized behavior may also be used to satisfy this definition. Since disorganized or aberrant behavior in the context of dementia is often attributable to cognitive impairment rather than a disturbance of reality testing, the presence of delusions or hallucinations was required for the diagnosis of psychosis. Delusions and hallucinations were also defined as described in *Diagnostic and Statistical Manual of Mental Disorders-III-Revised.*[25] A delusion was defined as "a false personal belief based on incorrect inference about external reality and firmly sustained in spite of what almost everyone else believes and in spite of what constitutes incontrovertible and obvious proof or evidence to the contrary." Moreover, "the belief is not one ordinarily accepted by other members of the person's culture or subculture." A hallucination is "a sensory perception without external stimulation of the relevant sensory organ." In our assessments, persistent misidentification syndromes were invariably associated with paranoid delusions and therefore did not present a practical problem in establishing the presence of psychosis. Psychotic symptoms that emerged only in the context of delirium were not included. The definition of psychosis employed in this study is similar to that employed in previous studies of psychosis in demented patients.[2-5] Since the *Diagnostic and Statistical Manual of Mental Disorders-III-Revised* is ambiguous about the affective and vegetative symptoms required for establishing the diagnosis of primary degenerative dementia of the Alzheimer type "with depression," the criteria for major depression were employed. The 27 subjects enrolled in our investigation were included in a previously published longitudinal study of the emergence of psychosis and depression in AD.[4]

Neuropathologic Methods

All brains were removed by a neuropathologist as a first procedure for the autopsy as previously described.[6,23,33,34] After weighing the unfixed brain, the brain stem and cerebellum were separated by intercollicular section. The cerebral hemispheres were initially sectioned in the coronal plane at the anterior border of the optic chiasm and the infundibulum of the pituitary. The hemispheres were then sectioned at 1-cm intervals and cooled by ice to retard autolysis. The brain stem and cerebellum were sectioned in the transverse plane at 0.5-cm intervals. Uniform tissue samples for neurochemical studies were obtained from anatomic areas using a pituitary biopsy rongeur and frozen at −70°C until biochemical studies were performed. After sampling for neurochemical studies, the brain sections were fixed flat in buffered 4% formaldehyde solution for at least 2 weeks. Tissue blocks for light microscopy were then obtained from undisturbed sections corresponding as exactly as possible to the areas adjacent to those sampled for neurochemical studies. Following standard tissue processing and paraffin embedding, a general survey was made with hematoxylin-eosin-stained sections, and 8-μm-thick sections stained with the Bielschowsky silver impregnation method were evaluated. Selected sections were also stained with congo red for amyloid and with a combined Nissl-myelin technique, with the Masson trichrome stain, and for glial fibrillary acidic protein.

Morphometry of coded samples was performed by neuropathologists who were unaware of the associated demographic and clinical information. The densities of SP and NFT per magnification field (×200) were determined for the middle frontal and superior temporal cortex, as well as the prosubiculum and entorhinal cortex of the hippocampus, as previously described.[33,34] Estimates of repeated-rater and inter-rater reliability were 0.84 or greater, and have been described in detail elsewhere.[33,34]

Neurochemical Methods

In addition to the four cortical regions subjected to morphometry, neurochemical analysis was performed on tissue obtained from the substantia nigra, thalamus, amygdala, and caudate nucleus. The concentrations of the neurotransmitters norepinephrine (NE), dopamine (DA), and serotonin (5-HT), as well as the NE metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG), the dopamine metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), and the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in brain tissue were determined by reversed-phase, high-pressure liquid chromatography with electrochemical detection as previously described.[35,36] The sensitivity of this analytic method was in the range of 0.05 to 0.10 pmol for the biogenic amines and their metabolites.

Since MHPG is largely present in conjugated forms in brain tissue, the measurement of this noradrenergic metabolite required an initial hydrolysis step for quantitative recovery.[37] Samples of brain tissue (20- to 40-mg samples) were homogenized in 15 volumes of 1 N acetic acid containing 3,4-dihydroxybenzylamine as an internal standard. After 15 minutes at 4°C, the resulting homogenates were adjusted to pH 4 by the addition of 6 N sodium hydroxide (6 μL/300 μL homogenate), clarified by centrifugation at 30 000 g for 10 minutes at 4°C, and analyzed by reversed-phase high-pressure liquid chromatography.

For the remaining neurochemical determinations, tissue samples were homogenized at 4°C in 9 volumes of 75 mmol/L of phosphate buffer (pH 7.4) containing freshly added 3,4-dihydroxybenzylamine as an internal standard, and aliquots were removed for the measurement of choline acetyltransferase (EC 2.3.1.6) activity. The remainder of each homogenate was immediately acidified to pH 4 by a 1:3 dilution with freshly prepared mobile-phase lacking acetonitrile (100 mmol/L of sodium phosphate, 1 mmol/L of 1-heptanesulfonic acid, and 1 mmol/L of ethylenediaminetetraacetic acid, adjusted to pH 2.9 with saturated citric acid) to ensure the stability of the biogenic amines and their metabolites. Inclusion of the internal standard at the time of homogenization control for any degradation of the biogenic amines that may have occurred during the interval at neutral pH and 4°C. Separate control experiments indicated that less than 10% degradation occurred under these conditions. The resulting suspensions were homogenized again and clarified by centrifugation at 33 000g for 10 minutes at 4°C. The protein concentrations of the pellets were determined by the method of Lowry and coworkers.[38] The supernatants were used directly to determine the tissue concentrations of the neurotransmitters and metabolites, with the exception of NE, which could not be satisfactorily resolved from the solvent front. Instead, NE was adsorbed from an aliquot of each supernatant with alumina and recovered by extraction of the alumina with 0.1 N perchloric acid. The concentration of NE was determined using the resulting perchloric acid extracts. For each brain, the concentrations of these compounds in corresponding regions from the left and right hemispheres were averaged and expressed as picomoles per milligram of protein.

Choline acetyltransferase activity was assayed in tissue homogenates by a minor modification of Fonnum's method,[39] as previously described.[23,34] The 40-μL reaction mixtures contained 20 μL of homogenate and 20 μL of a solution of 600 mmol/L of sodium chloride, 40 mmol/L of magnesium chloride, 2 mmol/L of eserine, 50 mg/dL of bovine serum albumin, 0.73 mmol/L of [acetyltritium]-coenzyme A (5.52 mCi/mmol), and 5 mmol/L of choline iodide in 75 mmol/L of phosphate buffer at pH 7.4. After incubation for 20 minutes at 38°C, the reactions were stopped by immersing the tubes in an ice bath. Labeled acetylcholine in each reaction mixture was extracted into 150 μL of 7.5% tetraphenylboron in 3-heptanone and quantified by scintillation spectrometry. Specific activities were calculated from duplicate assays and the average values from corresponding regions from the left and right hemispheres were expressed as nanomoles of acetylcholine synthesized per hour per milligram of protein.

Statistical Analysis

The sex ratios in the groups of patients with or without psychosis were compared using Fisher's Exact Test. Mean values of the continuous clinical, morphometric, and neurochemical variables were compared using the Mann-Whitney-Wilcoxon rank sum test. Two-tailed tests of significance were employed.

†Statistically significant difference.

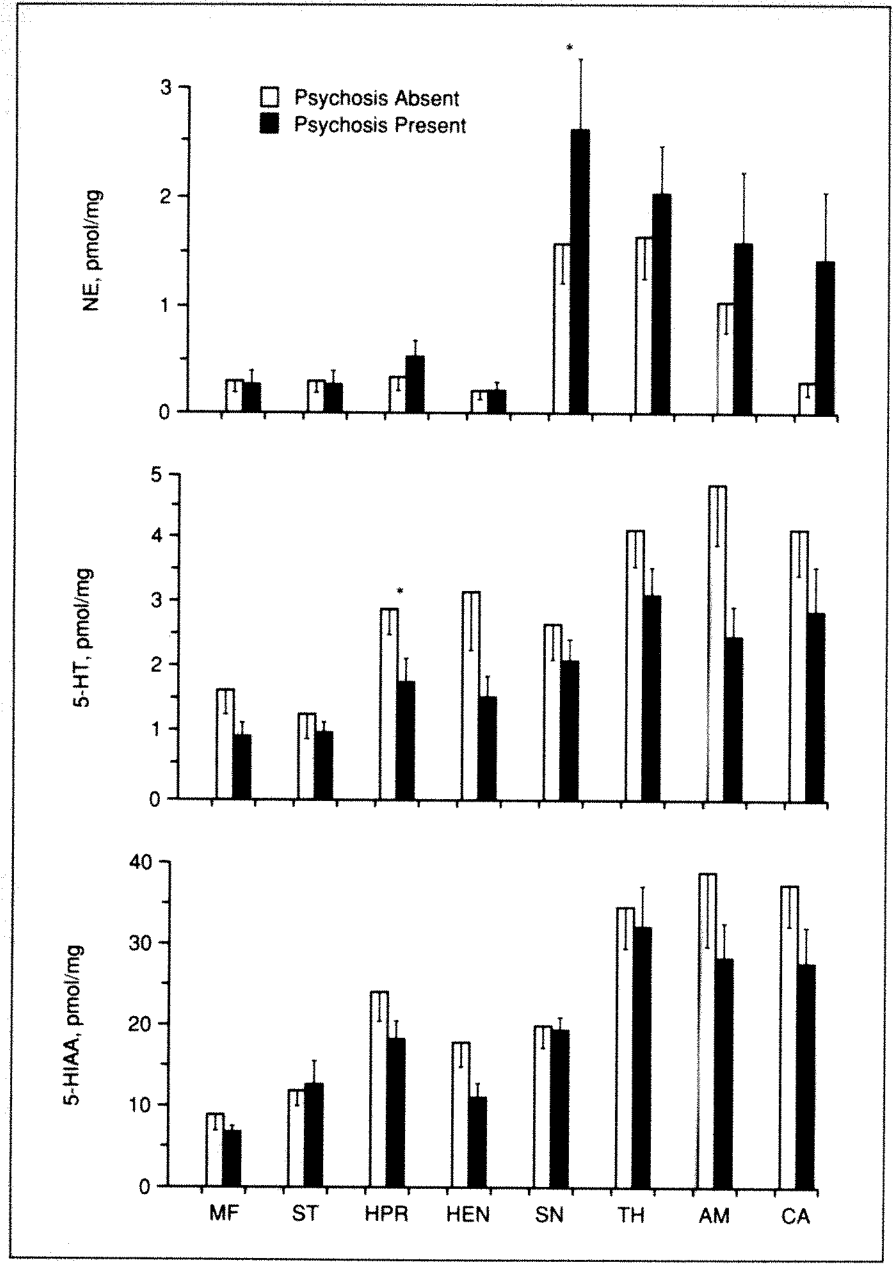
RESULTS

All 27 subjects included in the study suffered from histologically confirmed AD, as determined at autopsy. Demographic and clinical characteristics of the study sample are presented in Table 1. Thirteen of the patients (48%) developed psychosis, as defined by the emergence of delusions or hallucinations, between the onset of dementia and death. Psychosis remitted in only two of these 13 cases prior to death. The observed prevalence of psychosis was consistent with previously reported results from other prospective studies of behavioral syndromes in AD.[3,4] Ten of the 27 patients also met criteria for major depression, but were nearly equally distributed between the groups with (n = 6) and without (n = 4) psychosis. As a group, patients who developed psychosis did not differ significantly in sex ratio, mean age at death, mean age at onset of dementia symptoms, mean duration of illness, mean postmortem interval, or mean brain weight, from those who did not develop psychosis.

The relationship of psychosis to the cortical densities of SP and NFT is described in Tables 2 and 3. The development of psychosis was associated with significant increases in the mean densities of SP and NFT in the prosubiculum and middle frontal cortex, respectively. Trends toward increases in the densities of these morphologic lesions were also observed in the other three cortical regions examined.

In addition to the four cortical regions subjected to morphometric analysis, the concentrations of the neurotransmitters NE, DA, and 5-HT, their major metabolites, and the specific activity of choline acetyltransferase were quantified in the substantia nigra, thalamus, amygdala, and caudate nucleus. The results of the brain regional analysis of NE, 5-HT, and 5-HIAA are presented in the Figure. Psychosis was associated with a significantly greater concentration of NE in the substantia nigra that was accompanied by trends in this direction for the three remaining subcortical areas and two of the four cortical regions. The levels of MHPG were determined in the middle frontal and superior temporal cortex, entorhinal cortex, and caudate nucleus, for which adequate brain tissue was available. Psychosis was associated with trends toward



Noradrenergic and serotonergic correlates of psychosis in Alzheimer's disease were examined in the middle frontal (MF) and superior temporal (ST) cortex, prosubiculum (HPR) and entorhinal cortex (HEN) of the hippocampus, substantia nigra (SN), thalamus (TH), amygdala (AM), and caudate nucleus (CA). Mean values are presented as histobars with standard errors. Statistically significant comparisons ($P<.05$) are marked by an asterisk. Metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG) concentrations were determined only for the MF, ST, HEN, and CA regions. Respective mean levels of MHPG (±SE) in picograms per milligram were 0.84 ± 0.21, 0.97 ± 0.29, 1.19 ± 0.30, and 0.76 ± 0.15 for patients without psychosis; 0.85 ± 0.30, 1.04 ± 0.28, 1.54 ± 0.41, and 0.86 ± 0.25 for patients with psychosis. 5-HIAA indicates 5-hydroxyindoleacetic acid; 5-HT, serotonin; and NE, norepinephrine.

greater MHPG levels in all four of these regions, no one of which reached statistical significance. The emergence of psychosis was also associated with a statistically significant reduction of 5-HT in the prosubiculum that was accompanied by trends toward reduced levels of 5-HT and its metabolite 5-HIAA in all eight brain regions studied. In contrast to these results, psychosis was not associated with a significant change in the level of DA, its metabolites DOPAC and HVA, or choline acetyltransferase specific activity, in any of the brain regions studied.

Six (43%) of the 14 nonpsychotic patients and 10 (77%) of the 13 psychotic patients were receiving neuroleptic medications (haloperidol, thioridizine, or perphenazine) at the time of death. To assess the effects of neuroleptic medications on the neurochemical variables studied, the cases were stratified by whether or not neuroleptic medications were being administered prior to death and the mean values of these variables were compared. No significant effects of neuroleptic exposure were detected, nor were consistent trends observed. Therefore the psychosis-related alterations in the concentrations of these biogenic amines did not appear to have resulted from neuroleptic exposure.

COMMENT

In our prospective clinicopathologic study of AD, the occurrence of psychosis was associated with increased densities of SP and NFT in the cortex compared with the patients who did not develop psychosis. In AD, the density of SP in the neocortex typically exceeds that found in the allocortex, while the reverse is true for NFT. In this study, the greatest increases in SP and NFT were found in the allocortex and neocortex, respectively, tending to reduce the typical disparities in lesion density between these brain areas. The significance of this finding is unclear, but it is a pattern previously reported to be associated with an earlier age onset of dementia.[40]

The finding that psychosis was associated with significantly greater levels of NE in the substantia nigra, with similar trends in other brain areas, warrants further considerations. Since these values were similar to those observed in brains from elderly control subjects who had no history of neurologic disease prior to death,[23] this finding would seem to have resulted from the relative preservation of NE levels rather than an increase in the levels of their neurotransmitters. This result suggests the existence of a minimum threshold of noradrenergic functioning that is required for the expression of psychosis. Therefore, adrenergic antagonists may have a role in the treatment of certain demented patients with agitated psychosis. We have previously reported a summary of the results of an open trial of propranolol, in which a significant fraction of such patients exhibited clinical improvement.[41]

A comparison of the clinical, neuropathologic, and neurochemical features of psychosis and major depression in the context of primary dementia is presented in Table 4.[3-8,23,42] In our studies of behavioral syndromes in primary dementia, neither patients with psychosis[4] nor those with major depression[6] exhibited an age of onset of dementia that differed significantly from that of patients who did not develop these syndromes. How-

Table 4.—Comparison of Clinical, Neuropathologic, and Neurochemical Correlates of Psychosis and Major Depression in Primary Dementia*

	Psychosis	Major Depression
Sex, age at onset, duration of illness, brain weight	No change[3,4]	No change[6-8,41]
Mortality rate	No change[3,4]	Increased?[6,7]
Rate of cognitive decline	Increased[3-5]	No change[8]
Cortical SP and NFT	Increased SP in HPR and increased NFT in MF; trends toward increases of SP and NFT in remaining areas†	No change[6]
Degeneration of LC and SN	No change[7]	Increased[6]
Norepinephrine	Increased in SN; trends toward increases in five of seven remaining areas†	Decreased in neocortex and allocortex; trends toward decreases in all areas[23]
Serotonin	Reduced in HPR; trends toward decreases in remaining areas†	Trends toward decreases in all areas[23]
Dopamine	No change†	Increased in HPR; no consistent trends in other areas[23]
Choline acetyltransferase activity	No change†	Relative preservation in TH, AM, and CA; trends in same direction for most remaining areas[23]

*Changes are expressed relative to demented patients without the respective behavioral syndrome. Densities of senile plaques (SP) and neurofibrillary tangles (NFT) were determined in the middle frontal (MF) and superior temporal cortex, and the prosubiculum (HPR) and entorhinal cortex (HEN) of the hippocampus. In addition to these areas, neurochemical analysis was performed in the substantia nigra (SN), thalamus (TH), amygdala (AM), and caudate (CA) nucleus. LC indicates locus ceruleus.

†Data cited from our study.

ever, the relationship of these behavioral syndromes to the age at onset of cognitive impairment among demented patients is controversial. One reason for this may lie in the limitations inherent in making retrospective estimates of the age when cognitive decline begins. Moreover, the resolution of this issue is likely to require population-based studies, so that the potential sampling bias favoring the referral of patients whose functioning is disproportionately impaired by behavioral disorders can be avoided.

Several investigations, including two prospective longitudinal studies,[3,4] have found that psychosis is associated with an increased rate of cognitive decline among patients with primary dementia, although the presence of psychosis did not significantly affect the mortality rate. In contrast, major depression does not appear to affect the rate of cognitive decline in patients with clinically diagnosed AD.[8] Instead, two studies have suggested that the emergence of major depression may be associated with an increase in the rate of mortality among patients with primary dementia.[6,7]

Substantial differences also become apparent when comparing the reported neuropathologic and neurochemical correlates of psychosis and major depression in the context of primary dementia. In this study, psychosis was associated with increased neurodegenerative changes in the cortex, but neither the neurochemical evidence presented here, nor previously published morphometric data,[7] found psychosis to be associated with increased degeneration of subcortical aminergic nuclei. In contrast, we previously reported that major depression in primary dementia is associated with increased degeneration of the locus coeruleus and substantia nigra, but not increased numbers of morphologic lesions in the neocortex or allocortex.[6] Furthermore, the profiles of neurochemical changes associated with psychosis and major depression[23] differ considerably, except for the suggestion of modest generalized decrements in 5-HT and 5-HIAA that occur in both behavioral syndromes and may be nonspecifically related to behavioral stress. In summary, the neuropathologic and neurochemical correlates of psychosis and major depression that we describe are selective; each syndrome is associated with distinctive morphometric and neurochemical changes in specific brain regions (Table 4).

The neuropathologic and neurochemical changes associated with psychosis and major depression in primary dementia are probably important determinants of prognoses in these syndromes, as well as the symptoms of the syndromes themselves. Increased densities of SP and NFT in the cerebral cortices of patients with psychosis may be directly related to the increased rate of cognitive decline observed in this subgroup.[3-5] In addition, cortical degeneration itself may render psychosis in primary dementia less likely to undergo spontaneous remission and less responsive to pharmacotherapy than the idiopathic psychoses that typically occur earlier in life. In a prospective longitudinal study of AD, the persistence of psychotic symptoms over time was evident even when neuroleptic drugs were prescribed.[4] However, even increased degenerative cortical changes may not be associated with decreased longevity when the fundamental necessities of life are provided in a supervised nursing care environment, as was the case for the majority of our patients.

Major depression in primary dementia does not appear to be associated with increased degeneration of the cerebral cortex or an increased rate of cognitive decline.[6,8] However, the selective degeneration that occurs in the brain stem may also indicate that other physiologic functions, including swallowing, respiration, and cardiovascular homeostasis, may be affected because other brainstem centers are also involved. In the absence of extracorporeal life support devices, such dysfunctions are likely to increase mortality even when complete custodial care is provided. This hypothesis may also explain the observation that the development of sleep apnea, presumed to be related to dysfunction or degeneration of brain-stem structures, is predictive of increased mortality among elderly patients with idiopathic major depression.[43]

As demonstrated by our studies of major depression[6,23] and psychosis, the presence of behavioral syndromes may have significant effects on measures of morphologic and neurochemical pathology in degenerative brain disease. We therefore recommend that clinical descriptions of patients employed in such studies include assessments of psychiatric syndromes and that study designs control for the potential effects of these disorders.

Regional Cerebral Blood Flow After Human Cardiac Arrest

A Hexamethylpropyleneamine Oxime Single Photon Emission Computed Tomographic Study

Risto O. Roine, MD; Jyrki Launes, MD; Päivi Nikkinen, Lic Phil;
Lena Lindroth, MSc; Markku Kaste, MD

• We studied 30 patients 24 hours after out-of-hospital cardiac arrest and 13 age-matched normal controls with the use of technetium Tc 99m–hexamethylpropyleneamine oxime single photon emission computed tomography. All patients were followed up for 12 months or until death. Frontal hypoperfusion (anteroposterior perfusion ratio, <0.90) was observed in 23 patients (77%). In eight patients who remained comatose and died, the total size of perfusion defects was larger (38% ± 20%) than in the 21 patients who recovered consciousness (24% ± 14%), but the anteroposterior ratio was similar in both of these patient groups (0.83 ± 0.09) and significantly lower than in the controls (0.96 ± 0.03). During follow-up, both the anteroposterior perfusion ratio and the relative defect size improved, but frontal hypoperfusion was still observed in seven of 13 patients. After cardiac arrest, regional cerebral blood flow is characterized by frontal hypoperfusion that tends to improve over time but that persists in most patients.

(*Arch Neurol.* 1991;48:625-629)

The recovery of cerebral blood flow (CBF) is essential for the survival of cardiac arrest victims. In experimental animal models, global cerebral ischemia can result in generalized or patchy hypoperfusion.[1,2] Multifocally reduced CBF following cardiac arrest has recently been reported by stable xenon computed tomographic and microsphere methods in dogs without correlation to neurological outcome.[3,4] The regional distribution of CBF (rCBF) after human cardiac arrest is still unknown. Neither is it known whether changes in postischemic CBF have any correlation with recovery of consciousness or outcome. Delayed restoration of spontaneous circulation has been shown to be detrimental to the recovery of CBF.[5,6]

Single photon emission computed tomography (SPECT) and lipophilic tracers, especially technetium Tc 99m–hexamethylpropyleneamine oxime (HMPAO), have been used clinically in the evaluation of various conditions such as stroke,[7,8] epilepsy,[9] dementia,[10] subarachnoid hemorrhage,[11] encephalitis,[12] and brain death.[13,14] HMPAO readily crosses the blood-brain barrier and has a high first-pass cerebral extraction with satisfactory retention for imaging purposes.[15,16] Some studies suggest that HMPAO SPECT may be useful in predicting the outcome of stroke,[8,17] but contradictory results have also been published.[18,19]

We studied the rCBF in 30 patients who had been resuscitated from out-of-hospital ventricular fibrillation 24 hours after cardiac arrest, and we repeated the examination several weeks later using ^{99m}Tc-HMPAO and SPECT. The aims of this study were as follows: (1) to find out whether a characteristic pattern of CBF exists after human cardiac arrest; (2) to see how the regional flow changes during follow-up; (3) to evaluate the prognostic value of SPECT in the acute postarrest stage; and (4) to study the effect of a calcium entry–blocking drug, nimodipine, on the rCBF after cardiac arrest.

PATIENTS AND METHODS

We studied 30 patients (mean [± SD] age, 65 ± 12 years) 24 ± 2 hours after resuscitation from out-of-hospital ventricular fibrillation, and 13 age-matched normal controls without diagnosed cerebral disorders (mean [± SD] age, 64 ± 6.5 years). All patients included in the study had been recruited in a placebo-controlled double-blind trial of nimodipine in the treatment of out-of-hospital ventricular fibrillation, in which a total of 155 patients were enrolled.[20] Seventeen patients received a continuous infusion of nimodipine in a dosage of 0.5 μg/kg per minute for 24 hours and 13 received placebo. Informed consent was obtained from a family member of the patient. During the first 24 hours after cardiac arrest, all patients were treated according to a standardized, brain-oriented intensive care protocol. All patients received controlled ventilation during SPECT with a mean arterial Pco$_2$ of 31 ± 5.6 mm Hg. The duration of arrest without cardiopulmonary resuscitation was 5.6 ± 2.1 minutes, and spontaneous circulation was restored in 18.3 ± 5.2 minutes after arrest time. The level of consciousness of each patient at the time of SPECT was assessed using the Glasgow Coma Scale.[21]

Single photon emission computed tomographic imaging was performed with a rotating large field-of-view gamma camera (General Electric 400T, General Electric, Hoersholm, Denmark) equipped with a low-energy all-purpose parallel hole collimator. Three hundred seventy to seven hundred forty megabequerels of HMPAO labeled with technetium Tc 99m and 30 seconds per frame was used. Filtered back projection algorithm using a modified Shepp-Logan filter

*A/P ratio denotes the activity ratio of frontal and occipital brain regions; defect %, the total relative size of supratentorial perfusion defects; P, placebo, Pco$_2$, arterial blood carbon dioxide partial pressure during SPECT; GCS, Glasgow Coma Score during SPECT; GOS, Glasgow Outcome Score at 1 year; MMSE, Mini-Mental State Examination at 1 year; R, right; L, left; NA, not available; and CBF, cerebral blood flow.

was used for producing a set of eight 15-mm-thick transversal tomographic slices from the orbitomeatal line upwards. The data acquisition was started 2 minutes after the injection of the tracer into an antecubital vein. A second scan was performed on 13 patients an average of 145 days later (range, 9 to 437 days).

As absolute rCBF cannot be measured by this technique, a comparison of count rates between hemispheres and the relative rCBF values using cerebellum as an intraindividual reference are commonly used semiquantitative indexes of regional abnormalities of blood flow. However, bilateral or diffuse perfusion defects expected to occur after global cerebral ischemia may remain unnoticed by such methods. Thus, we used two other indexes of rCBF: (1) the total size of perfusion defects (ie, defect percentage), expressed as percentage of the total supratentorial brain volume as determined visually and measured by planimetry; and (2) the anteroposterior perfusion (A/P) ratio, expressed as the ratio of the count-rates in frontal and occipital thirds of four superimposed supratentorial slices. An A/P ratio below 2 SDs of the mean of age-matched controls (ie, <0.90) was considered to indicate frontal hypoperfusion.

Computed tomography (12 studies) or low-field magnetic resonance imaging (10 studies) was performed more than 2 weeks after arrest on 15 patients. Seven patients underwent both studies.

All patients were followed up for 12 months or until death. At 12 months, a neurological examination, Mini-Mental State Examination,[22] neuropsychological examinations, and assessment of activities of daily living functions and quality of life were performed for survivors. These findings will be reported separately. The 1-year outcome of all survivors was graded using the Glasgow Outcome Scale.[23]

All values are expressed as means ± SDs and/or 95% confidence intervals (CI). For statistical comparison of group means, unpaired or paired *t* tests with two-tailed *P* values and 95% CI of the mean were used for continuous variables.

RESULTS

In the first study, SPECT was abnormal in 28 patients and normal in only two patients (Table 1). One patient (case 26) with complete lack of intracranial circulation and brain death was excluded from further statistical analysis. The mean relative size of the perfusion defect was 29.9% ± 20.9% (95% CI, 22.0 to 37.7). The mean A/P ratio was 0.83 ± 0.09 (95% CI, 0.79 to 0.86) and was significantly lower than in age-matched controls (0.96 ± 0.03; 95% CI, 0.94 to 0.98, *P*<.001) (Table 2, Fig 1). Frontal hypoperfusion (A/P ratio <0.90) was observed in 23 patients

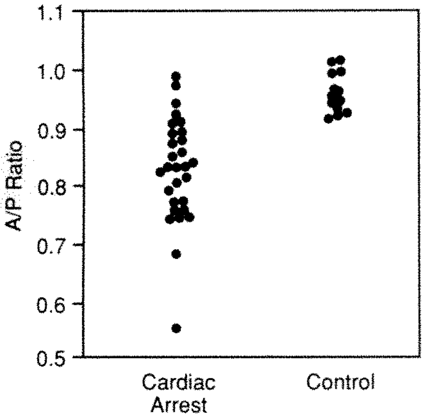

Fig 1.—Anteroposterior perfusion ratio (A/P ratio) in 29 patients who suffered cardiac arrest 24 hours after arrest and in 13 age-matched controls.

(77%) (Fig 2), a single perfusion defect was observed in 10 patients (33%), and two to five defects were observed in nine patients (30%) (Table 1). The localization of separate perfusion defects varied widely. Crossed cerebellar diaschisis was observed in nine patients.

Nine patients remained comatose and died, whereas 21 patients recovered consciousness. The mean duration of coma was 50 hours (range, 2 hours to 56 days). Seventeen patients survived for at least 1 year. In eight patients dying while in a comatose state, the perfusion defect was larger (38%±20%) than in the 21 patients who recovered consciousness (24%±14%, $P=.035$) (Table 2). However, the perfusion defect size did not correlate with the Glasgow Outcome Score at 1 year after cardiac arrest.

In the second study, both the A/P perfusion ratio and the relative defect size had improved, but frontal hypoperfusion was still present in seven of 13 patients (Table 3). The A/P ratio was below 0.80 in only one patient (case 10) in the second SPECT. She had a severe anoxic encephalopathy leading to death 294 days after the arrest. Another patient with good outcome (case 16) had an A/P perfusion ratio of 0.55 at 24 hours after arrest and 0.83 after 3 months. Five of the seven patients with frontal hypoperfusion still present in the second study reached the best Glasgow Outcome Score at 1 year, one patient (case 6, A/P perfusion ratio of 0.80) had a moderate disability, and one patient (case 10, A/P perfusion ratio of 0.78) had a severe disability. Neither the A/P perfusion ratio nor the defect size correlated with patient age, the arrest time, the duration of resuscitation, or the arterial P_{CO_2} at the time of imaging.

Table 2.—Anteroposterior Perfusion Ratio (A/P Ratio) and Relative Size of Perfusion Defect Expressed as a Percentage of All the Supratentorial Slices in HMPAO SPECT (Defect %) in Patients Recovering Consciousness After Cardiac Arrest and in Those Remaining Comatose Until Death*

Table 4.—Mean Perfusion Defect Size (Defect %) and Anteroposterior Perfusion Ratio (A/P Ratio) After Cardiac Arrest in Patients Receiving Nimodipine or Placebo*

	Nimodipine (N = 16)	Placebo (N = 13)
Defect, %	29.5 (21.0-38.0)	24.9 (15.4-34.4)
A/P ratio	0.81 (0.76-0.85)	0.85 (0.80-0.90)

*The numbers in parentheses are 95% confidence intervals.

Of the 17 patients surviving for at least 1 year, 14 had frontal hypoperfusion and three did not have this finding at 24 hours after arrest. Frontal hypoperfusion was as common and as severe in surviving patients as in those remaining comatose until death (Table 2). Thus, frontal hypoperfusion did not predict the outcome. The mean Mini-Mental State Examination score for all 1-year survivors was 26.6±5.6 (95% CI, 23.7 to 29.5), which is in the normal range. The performance in the Mini-Mental State Examination at 1 year after cardiac arrest had no significant correlation to the results of SPECT (Table 1).

Computed tomography revealed vascular lesions in six patients, correlating exactly with the perfusion defect observed in the early SPECT in one patient only. Furthermore, the perfusion defects observed in SPECT corresponded to the vascular lesions found in later magnetic resonance imaging studies in only one of four patients. Both the defect percentage and the A/P ratio were slightly more abnormal in patients receiving nimodipine than in patients receiving placebo, although this difference was not significant (Table 4).

COMMENT

In this study, we detected in most patients 24 hours after cardiac arrest a typical rCBF pattern of frontal hypoperfusion that ameliorated over time but persisted in many cases. Also, the relative size of the total perfusion defect improved in recovering patients. Although permanent unconsciousness was usually associated with a large volume of poorly perfused brain, only the largest perfusion defects seemed to predict irreversible coma. All four patients with a total perfusion defect size of more than 50% of the supratentorial brain remained comatose and died. In the total group of patients who had suffered cardiac arrest, even large perfusion defects (up to 42%) did not exclude the possibility of good recovery and thus the number or size of separate perfusion defects was not a reliable predictor of outcome. The occurrence or severity of frontal hypoperfusion did not predict either the recovery of consciousness or the outcome.

The significance of postischemic hypoperfusion is still equivocal in humans. Based on animal experiments, it is not known whether postischemic hypoperfusion is the cause or the consequence of delayed neuronal injury. Frontal hypoperfusion disappearing in parallel with recovery has previously been reported in patients with posttraumatic coma using the xenon 133 inhalation technique.[24,25] Recently, DeVolder et al[26] demonstrated a generalized decrease in glucose metabolism approximately 1 to 6 months after cardiac arrest in 12 patients by positron emission tomography and 2-[^{18}F] fluoro-2-deoxy-D-glucose. They found frontal hypometabolism in five of 12 patients, whereas a regional decrease in fluorodeoxyglucose uptake was more common in the parieto-occipital cortex (nine of 12 patients). In seven patients who underwent imaging scans while in a vegetative state, the mean cerebral glucose metabolism was about 50% of that observed in control patients.[26] Beckstead and coworkers,[27] using inhaled xenon and extracranial detectors, were the first to detect a decreased cortical CBF during the first 2 hours after arrest but a normal CBF 24 hours later in 25 patients. According to Forsman et al,[28] nimodipine increases postischemic CBF in man without an effect on neurological outcome. They demonstrated that the mean cortical CBF was only 13±1 mL/100 g per minute 3 to 4 hours after arrest in their series of 51 patients. The mean cortical CBF did not correlate with the recovery of consciousness, but nimodipine roughly doubled the mean CBF. The effect of nimodipine on the evolution of human cerebral infarction has also been studied by positron emission tomography.[29] Patients receiving intravenous nimodipine for 1 week after a hemispheric ischemic stroke had significantly higher rCBF values in the densely ischemic areas as compared with those receiving placebo. Although the aim of many therapeutic approaches has been to augment postischemic CBF, an increase in CBF has also been reported to be associated with irreversible brain damage and death after cardiac arrest.[30]

One of the goals of the present study was to find out the possible effect of nimodipine on the postischemic rCBF. We found no evidence of a beneficial effect of nimodipine on frontal postischemic hypoperfusion or rCBF as measured by the defect percentage after cardiac arrest. On the other hand, CBF changes occurring during the early postischemic phase as well as all quantitative changes in the mean CBF would have remained unnoticed in the present study.

Most regional perfusion defects imaged by SPECT in the early phase after cardiac arrest were not observed in later neuroradiological examinations, ie, did not lead to completed infarction. In general, the perfusion defect in SPECT is larger than the corresponding infarction visualized later with computed tomography or magnetic resonance imaging, which has been suggested to be associated with the capacity of SPECT to visualize the peri-infarct zone with reduced blood flow.[31]

In recovering patients, both the A/P perfusion ratio and the defect percentage improved significantly, but frontal hypoperfusion still remained in seven of 13 patients. Five patients had a good outcome despite the persisting frontal hypoperfusion and only those two with the lowest A/P perfusion ratios in the second study were disabled. The A/P ratio was the same in patients recovering consciousness and in those who did not. Furthermore, two of the eight patients remaining comatose until death after 16 or 39 days had a completely normal A/P ratio (0.94 and 0.99, respectively). Even recovering patients had a significantly worse A/P perfusion ratio in both short-term and late studies as compared with age-matched controls. According to the results of this study, a severe frontal hypoperfusion seems to be a characteristic finding after human cardiac arrest, although it is not always present. Additionally, frontal hypoperfusion did not seem to reflect coma as might be the case after head trauma.[24,25]

After cardiac arrest, the rCBF improves after the acute stage in recovering patients but may remain abnormal. Technetium Tc 99m–HMPAO SPECT may have some value as an additional prognostic indicator early after cardiac arrest. It is capable of visualizing poor circulation in extensive regions of the brain thereby suggesting bad outcome as well as the complete lack of intracranial circulation in brain death. Quantitative measurement of rCBF and metabolism is likely to provide more useful information of the potential of the brain to recover from global ischemia and to direct future attempts in cerebral resuscitation.

Sclerosing Vasculopathy of the Central Nervous System in Nonelderly Demented Patients

Melinda L. Estes, MD; Marc I. Chimowitz, MD; Issam A. Awad, MD;
James T. McMahon, PhD; Anthony J. Furlan, MD; Norman B. Ratliff, MD

• Three nonelderly patients without hypertension whose clinical and radiologic features otherwise resembled Binswanger's subcortical arteriosclerotic encephalopathy underwent biopsy of the hyperintense periventricular lesions seen on magnetic resonance imaging. The pathologic findings of the periventricular lesions consisted of gliosis with mild rarefaction and edema of the white matter. All patients had a sclerosing vasculopathy of unknown cause, which involved numerous small vessels within the periventricular lesions. The vessels stained negatively for amyloid, amyloid precursors, desmin, vimentin, keratin, immunoglobulin, and complement. On electron microscopy, small arteries, arterioles, venules, and capillaries were characterized by swollen astrocytic foot processes surrounding the vessels; dense, perivascular collagen packing; crystalline arrays of filaments within basement membrane; giant lipid-laden lysosomes within perivascular cells; and narrowing of the vascular lumina. Similar changes were not seen in a control group of 19 patients. The pathologic features of the vessels in these cases are distinct from the vasculopathy associated with Binswanger's subcortical arteriosclerotic encephalopathy. We suggest that a spectrum of vasculopathies may be associated with dementia and periventricular hyperintense lesions on magnetic resonance imaging.

(*Arch Neurol.* 1991;48:631-636)

Although numerous articles[1-9] have described the clinical, radiological, and pathological features of Binswanger's subcortical arteriosclerotic encephalopathy (BSAE) and although the white matter lesions in patients with BSAE are well documented, the vasculopathy associated with this syndrome is not well characterized. Most articles describe the vascular lesions as arteriosclerosis or lipohyalinosis, without providing ultrastructural details of the vessels. We had the opportunity to study three nonelderly patients without hypertension, in whom clinical and radiological features otherwise resembled BSAE. Examination of brain biopsy specimens obtained from these patients showed distinctive small-vessel lesions that were not seen in specimens from a control group of 19 patients undergoing stereotactic brain biopsy for other reasons. This article describes the clinical, radiological, and pathological features found in the three patients and focuses on the pathological features of the small vessels revealed by means of light and electron microscopic examination.

REPORT OF CASES

CASE 1.—A 48-year-old man was examined in 1988 for progressive dementia. He had a history of throbbing headaches since the age of 10 years, often associated with teichopsia, limb paresthesia, and aphasia. Several medications were prescribed for the headaches, including a combination of caffeine and ergotamine tartrate (Cafergot), methysergide maleate (Sansert), prednisone, and meperidine hydrochloride (Demerol). In 1974, at the age of 34 years, he suddenly developed right hemiparesis, which was persistent and unassociated with his typical migraine headache. In 1981, he was admitted to the psychiatric service for depression and opiate dependence. Neurological examination showed right-sided hyperreflexia and a right-sided Babinski sign. Cranial computed tomographic (CT) scan showed confluent periventricular lucencies. In 1983, he was readmitted to the psychiatric service for depression and opiate dependence. Previously normotensive, his blood pressure on admission was 150/65 mm Hg. His neurological examination results and CT scan were unchanged. A toxicologic profile was positive for amphetamines. By 1985, he had become forgetful and could not handle money. His memory deteriorated progressively, and he developed walking difficulties over the next 3 years, prompting readmission in 1988.

On examination in July 1988, his blood pressure was 125/85 mm Hg. His affect was bland, and responses to questions were slow. He thought it was July 1985. Speech was normal with naming, repetition, reading, and comprehension preserved. He recalled two of four objects at 5 minutes. There was decreased dexterity using the right hand, bilateral arm and leg spasticity with hyperreflexia and ankle clonus, and a right-sided Babinski sign. On walking, his steps were small, slow, and unsteady. Sensation was normal.

The results of cerebrospinal fluid examination, including immunoglobulin studies, were normal except for a slightly elevated

protein level (62 mg/dL). Magnetic resonance imaging (MRI) showed diffuse confluent areas of increased signal intensity in the periventricular region that contained discrete cystic lesions and mildly enlarged lateral ventricles (Fig 1). Three-vessel cerebral angiographic findings showed no evidence of occlusive disease. Uncertainty regarding the diagnosis prompted a right frontal craniotomy with biopsy of the frontal cortex, centrum semiovale, and periventricular region.

CASE 2.—In 1980, a 48-year-old normotensive woman, with long-standing throbbing headaches, developed dysarthria and began to drag her right leg when walking. In 1982, she was examined for excessive sleepiness and diminished short-term memory. Results of spinal fluid examination were normal, a cranial CT scan showed attenuation of the white matter in the frontal regions, and an electroencephalogram demonstrated frontal, intermittent, rhythmic delta activity. In 1982, a few episodes of confusion, drooling, dysarthria, and urinary incontinence were attributed to seizures prompting treatment with carbamazepine (Tegretol). Over the next 6 years, she developed progressive dementia, urinary incontinence, and difficulty walking.

On examination in 1988, she was inappropriately jovial, inattentive, thought it was 1967, and recalled none of three objects in 5 minutes. Naming, repetition, reading, and writing were relatively well preserved. She drew a clock poorly, but could pantomime simple motor tasks. Her speech was dysarthric, the jaw jerk was prominent, and her right side was moderately weak and spastic. The reflexes were brisk bilaterally, and a right-sided Babinski sign was present. Her gait was wide based, extremely slow, and she exhibited delayed hip flexion and circumduction of the right leg. Sensation was normal, except for diminished vibration appreciation at the ankles.

Spinal fluid examination revealed the following findings: glucose, 3.72 mmol/L; protein, 0.68 g/L; white blood cell count, 1×10^6/L; red blood cell count, 1×10^6/L; IgG, 0.06 (normal, 0.006 to 0.04); albumin, 0.36 (normal, 0.08 to 0.30), IgG-to-albumin ratio, 0.17 (normal 0.07 to 0.19); IgG synthesis, 3.1 mg/d (normal, 0 to 3.1 mg/d); and negative oligoclonal bands. A brain MRI showed diffuse confluent areas of increased signal intensity in the periventricular regions, mildly enlarged ventricles, and moderate cortical atrophy. Results of three-vessel cerebral angiography were normal. Uncertainty regarding the diagnosis prompted stereotactic brain biopsy of the right frontal periventricular region.

CASE 3.—A 40-year-old normotensive man was examined in 1988 for progressive dementia and walking difficulties. Nine years earlier, he was laid off work in an assembly plant. He became depressed, apathetic, and uninterested in social activities. His wife suspected that he was confused at times. At attempt to return to work in 1985 failed because of inability to do his previous job. His memory began to fail, his gait was unsteady, and he fell occasionally. His cognitive and gait difficulties progressed insidiously over the next 3 years, and, ocasionally, he was incontinent of urine.

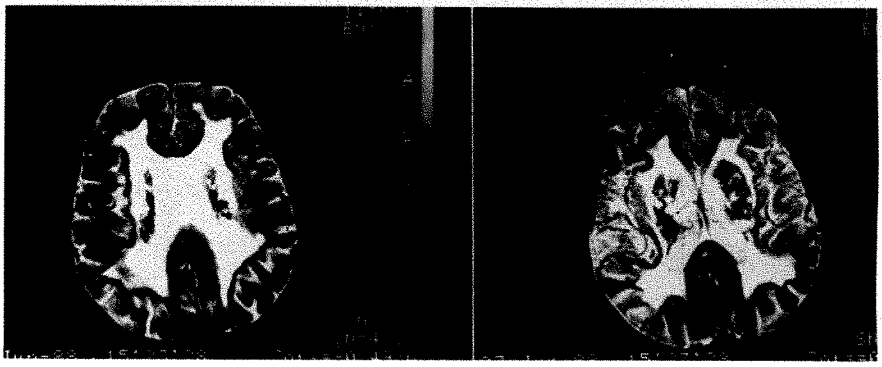

Fig 1.—Cranial T^2-weighted magnetic resonance imaging of patient 1, showing increased signal intensity in the periventricular region.

On examination, he was alert, but mentally slow. Speech, language, and praxis were normal. He could recall one of the three objects at 5 minutes and could not recollect the assassination of any president since his birth. The cranial nerves and reflexes were normal as were sensory examination results. Motor examination revealed normal power, tone, and muscle bulk, but fine finger movements, finger-to-nose, and heel-to-shin testing showed slight uncoordination. His walking was unsteady, without lurching or spasticity.

Laboratory data were normal for VDRL, human immunodeficiency virus antibody, serum cyanocobalamin, folate, urinary and serum arylsulfatase A, long-chain fatty acids, thyroid function tests, sedimentation rate, and antinuclear factor. Also an electromyograph (EMG) and sural nerve biopsy specimen revealed normal results. Cerebrospinal fluid examination showed the following findings: red blood cell count, 1×10^6/L; no white blood cells; protein level, 0.34 g/L; glucose level, 3.16 mmol/L; IgG, 0.03; albumin, 0.15; IgG synthesis, 4.8 mg/d (normal, 0 to 3.1 mg/d); IgG-to-albumin ratio, 0.23 (normal, 0.07 to 0.19); and negative oligoclonal bands. Magnetic resonance imaging showed confluent areas of increased signal in the periventricular regions, mild hydrocephalus, moderate cortical atrophy, and marked atrophy of the corpus callosum. An area of increased signal intensity in the right periventricular region was additionally examined by means of a stereotactic biopsy performed through a frontoparietal approach because of uncertainty regarding the diagnosis.

MATERIALS AND METHODS

Two patients underwent stereotactic brain biopsy, and one patient underwent an open biopsy. In all cases, several fragments of white-tan tissue were obtained. A portion of each specimen was snap frozen in liquid nitrogen for immunohistochemical analysis. The remaining tissue was divided and fixed in 3.75% glutaraldehyde for high-resolution light microscopic and electron microscopic examination or in Hollande's fixative for paraffin embedding.

Stereotactic biopsy was performed on at least three separate coordinates, spanning a total of 30 mm of tissue. The tissue was labeled as within, immediately outside, or remote from the periventricular hyperintense lesion (PHL). The tissue obtained at the time of open biopsy was labeled as periventricular white matter, subcortical white matter, and cortex.

A control group was formed based on review of 154 consecutive patients 18 years old or older who had stereotactic biopsies of radiographically identified lesions performed at the Cleveland (Ohio) Clinic Foundation between June 1987 and November 1989. Nineteen of these 154 patients had nonneoplastic lesions and were selected as control subjects. In these patients, a side-cutting biopsy instrument was used to obtain multiple 10 × 1-mm specimens for frozen section and permanent histopathologic examination. The specimens were processed as mentioned above.

Light Microscopy

Paraffin sections were cut at 5 μm, deparaffinized, and stained with hematoxylin-eosin, congo red, sulfonated alcian blue, crystal violet, Movat's pentachrome, alizarin red, Masson's trichrome, von Kossa's stain, periodic acid-Schiff, modified Kluver-Barrera stain, and Bodian staining.

Electron Microscopy

Tissue specimens for examination by means of high-resolution light microscopy and electron microscopy were fixed in 3.75% buffered glutaraldehyde for 2 hours and postfixed in 1% osmium tetroxide for 2 hours, and then they were embedded in Spurr's epoxy resin. Semithin (1-μm) plastic-embedded sections from all blocks were stained with a mixture of toluidine blue and basic fuchsin. Blocks for electron microscopic examination were selected, and thin sections were cut and subsequently stained with uranyl acetate–lead citrate. At least two blocks per case were examined using an electron microscope (Philips 400 T, Philips Electronics, Einhoven, The Netherlands).

Energy dispersive spectroscopy was performed on brain tissues routinely fixed and processed for electron microscopy as described above. Unstained sections, 60 to 80 nm thick, were mounted on beryllium grids and examined using an electron microscope (Philips 400 T) equipped with a roentgenographic detector and analyzer (EDAX/9100, Edax International Inc, Mahwah, NJ) and operated at 60 kV. Roentgeno-

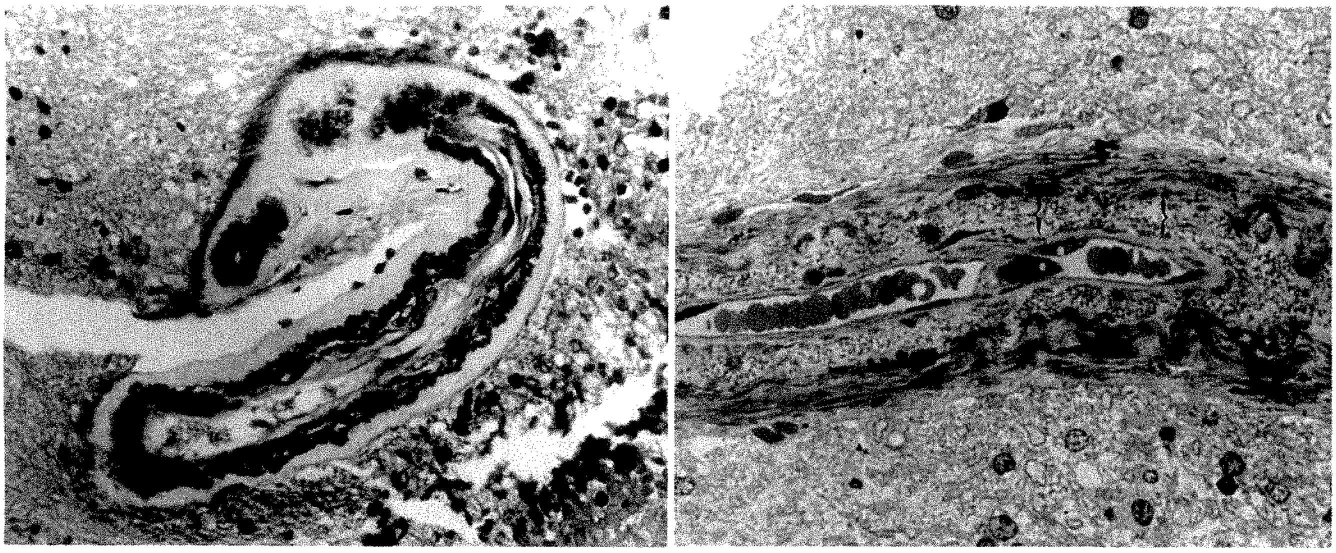

Fig 2.—Case 2. Left, Longitudinal section of a small artery from the deep white matter stained with Movat pentachrome. The normal thickness of the intima can be appreciated. The media is markedly thickened by a mixture of fibrillar connective tissue and black staining material that in this higher magnification photograph is clearly granular (original magnification ×206; final magnification ×540). Right, Longitudinal high-resolution light microscopic plastic section of a small artery from deep white matter stained with a mixture of toluidine blue and basic fuchsin. The intact endothelium and basal lamina can be seen. The medium is thickened and expanded by bundles of collagen that in the inner portion of the medium are randomly oriented and are running in a plane different from those in the outer portion of the medium. Membranous bodies suggestive of secondary lysosomes are present within the media (numerous bodies are enclosed within the braces). The adventitia of cerebral vessels is normally not well developed and cannot be identified in these vessels (original magnification ×160; final magnification ×430).

graphic spectra were accumulated for at least 90 seconds at a count rate of 1000 to 3000 cps, using a take-off angle of 20°.

Immunohistochemistry

Immunohistochemical examination was performed on both frozen and paraffin sections, using the avidin-biotin-complex technique with minor modifications for paraffin-embedded tissue.[10]

Antibodies

Antibodies used for frozen and paraffin sections examined immunohistochemically were as follows: desmin (Dako, Santa Barbara, Calif), glial fibrillary acidic protein (GFP, Dako), *mak*-6 (Triton, Alameda, Calif), vimentin (Dako), IgG, IgA, IgM-κ,-λ, -C3, and -C4 (Becton-Dickinson, Mountain View, Calif), and the amyloid precursor proteins, eg, serum amyloid A component and serum amyloid P component (Vector Laboratories, Burlingame, Calif).

RESULTS

Pathologic Findings

Light Microscopy.—All patients exhibited similar vascular changes. The majority of small vessels (80 to 300 μm) of all types, ie, arterioles, venules, and capillaries, were involved both within the PHL and in the cortex and meninges. In some of them, the vessel wall was strikingly thick and hyalinized (Fig 2, left). Masson's staining demonstrated a thick, concentric band of collagen within the vascular wall. Surrounding this was a clear space that contained variable numbers of convoluted, complex bodies that were variably eosinophilic or basophilic. These bodies were most readily visualized in metachromatically stained plastic sections, where they had the green-blue staining and membranous appearance of large secondary lysosomes (Fig 2, right). Capillaries with adjacent clear spaces and complex bodies, but without expansion of the vessel wall by connective tissue, were identified. In other small vessels, the wall was filled with lipid droplets. Stains for amyloid, including congo red, sulfonated alcian blue, and crystal violet, were negative in all cases, as were alizarin red and von Kossa's stains for calcium. Periodic acid–Schiff staining for glycogen was negative. The endothelium of all vessels was intact and did not appear affected by the process. Movat pentachrome staining demonstrated intact basal lamina and elastic lamina. The vessels were remarkably similar both within the same case and from one case to the next.

Immunohistochemical stains of the affected blood vessels for desmin, glial fibrillary acidic protein, *mak*-6, vimentin, and serum amyloid components A and B were negative. Stains for IgA and IgA-λ were positive in the intima, but not in the vessel wall.

Changes in the surrounding brain tissue were mild. The area corresponding to the PHL had gliosis with mild rarefaction and edema of the white matter. Vacuolization or other changes similar to the perivascular clear spaces were not seen in the surrounding brain tissue. Modified Kluver-Barrera staining demonstrated no demyelination, and Bodian staining revealed no senile plaques or neurofibrillary tangles. Pick bodies were not identified.

Electron Microscopy.—The findings by means of electron microscopic examination were similar in all three cases. The endothelial cells appeared unaffected by the process. The cellular junctions were intact, and the spacing appeared appropriate. Basal lamina and internal elastic lamina beneath the endothelium appeared normal. No inclusion bodies with zebra-body characteristics or other complex structure were observed.

Cells were identified partially surrounding the vessels. These cells had nuclei that conformed to the shape of the vascular wall and were partially invested with basal lamina. Within the cytoplasm of the cells were multiple large complex lysosomes, and numerous

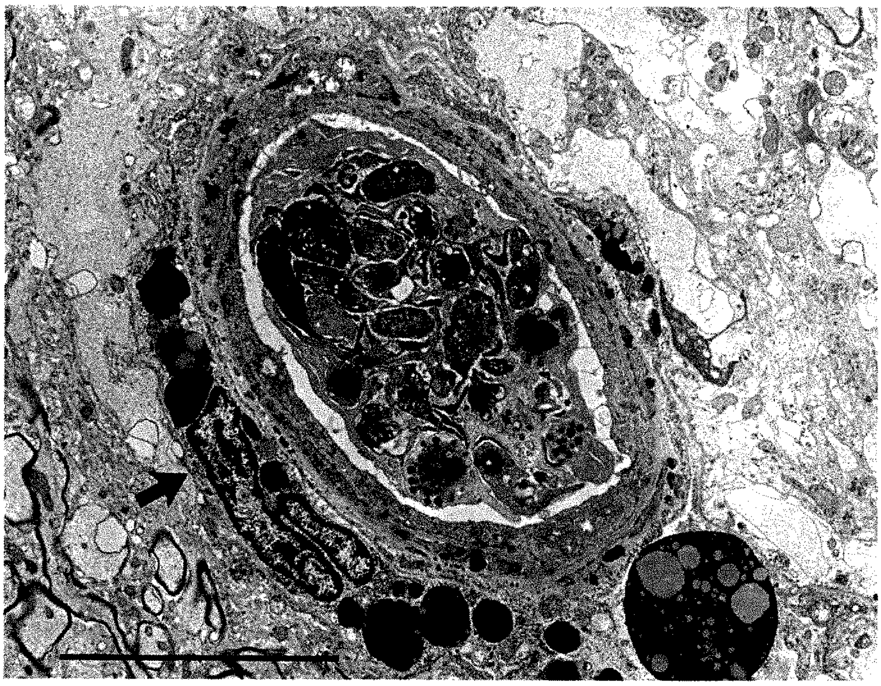

Fig 3.—Case 2. Electron micrograph of a cross-section of vessel double stained with uranyl acetate–lead citrate. A thrombus is seen within the lumen. Cells containing complex lysosomes and lipid are seen conforming to the vascular wall (arrow). The cells are at least partially invested with basal lamina. It is difficult to identify them unequivocally as either pericytes or macrophages. Bar indicates 10 μm.

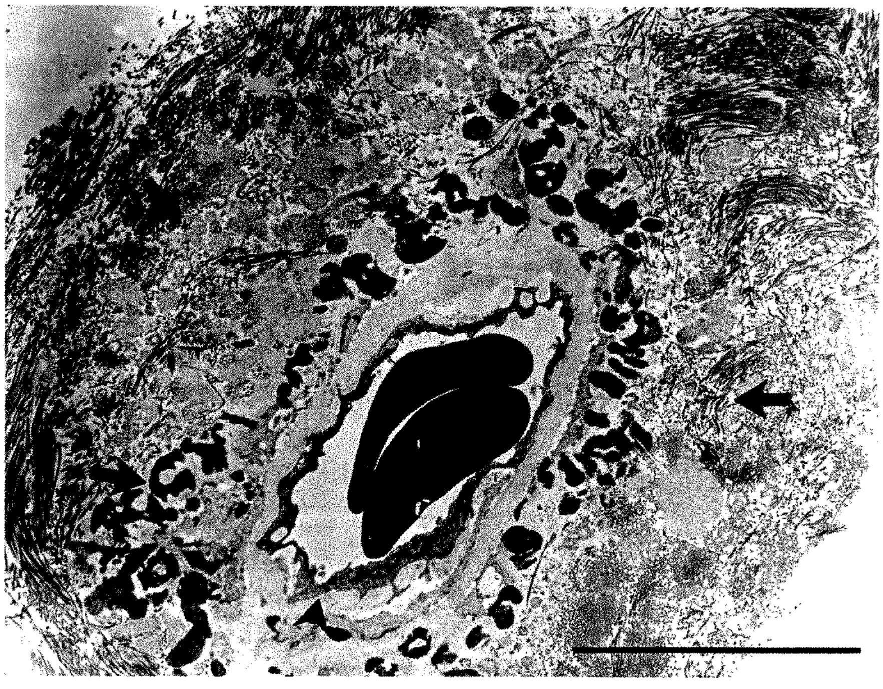
Fig 4.—Case 2. Electron micrograph of a cross-section of a small artery double stained with uranyl acetate–lead citrate. The endothelium and basal lamina appear intact (arrowhead). The remainder of the arterial wall, including all media and possibly the adventitia, is replaced by fragments of collagen, elastin, basal lamina, and granular electron-dense material (arrows). Bar indicates 10 μm.



large lipid droplets (Fig 3). Similar lysosomes were seen in cells that were separated from the vessel by a clear space. These latter cells had rounded nuclei and cytoplasmic filaments, and they were not invested by vascular basal lamina. The identity of either cell type was not clear; they could be pericytes, macrophages, glial cells, or all three.

The medium of these vessels was markedly thickened by layers of mature collagen mixed with fragments of elastin, basement membrane, and granular electron-dense extracellular material (Figs 4 and 5). The overall impression was that of a disorganized medial layer. Roentgenographic energy dispersive spectroscopy of this granular material and of the lysosomes indicated lack of metallic or mineral components. The entire thickness of the medium was involved. Smooth-muscle cells were absent and seemed to have been replaced by connective tissue or by lipid.

Many of the vessels were surrounded by swollen astrocytic foot processes containing filamentous material. These swollen processes correlated with the clear spaces noted by light microscopy. Splitting of the myelin lamellae was focally present.

Electron microscopic examination confirmed that the thickened vascular walls were composed of collagen, elastin fragments, basal lamina, and electron-dense material, or lipid. No amyloid or intermediate filaments were visualized by electron microscopy. Glycogen was not part of the thickened vascular wall as demonstrated by the negative periodic acid–Schiff staining. Findings by means of energy dispersive spectroscopy, special stains for calcium (alizarin red and von Kossa's stain), and immunohistochemical examination indicated that the extracellular granular electron-dense material was not mineral or metallic, glycogen, or immunoglobulin.

Diagnoses of the 19 patients in the control group (mean age, 38 years) who had nonneoplastic disease are summarized in the Table. No patient had vascular changes similar to those identified in our three patients.

COMMENT

Our three patients had similar clinical and radiological features, including progressive dementia, abnormal gait, spasticity (two patients), urinary incontinence (two patients), preservation of sensory modalities, confluent PHL identified on MRI, and mild ventricular enlargement. The pathological features of the PHL seen on MRI were characterized by gliosis with mild rarefaction and edema of the white matter and a predominantly white matter vasculop-

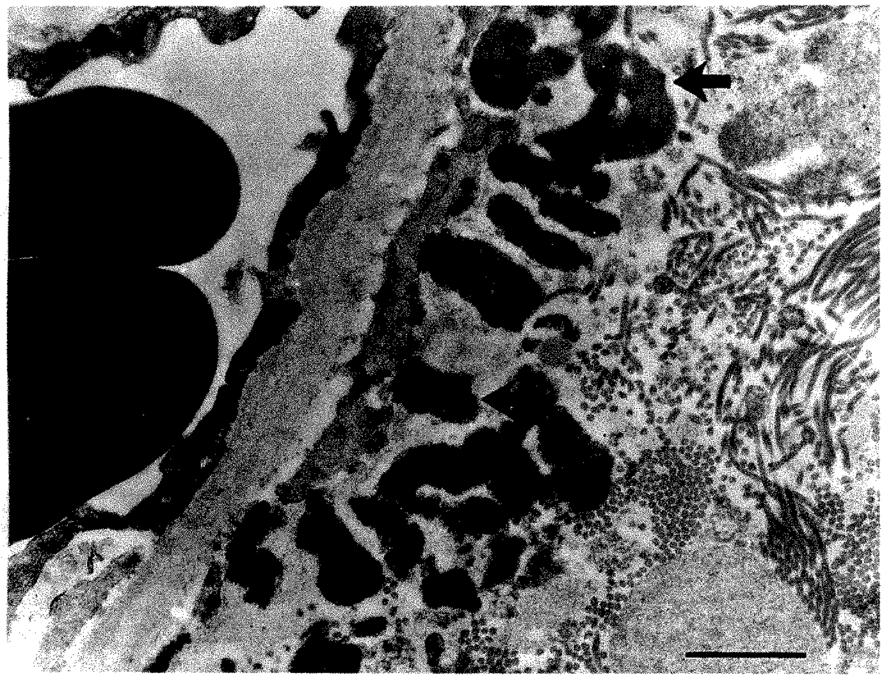


Fig 5.—Case 2. A high-magnification electron micrograph of the granular electron-dense deposits double stained with uranyl acetate–lead citrate. These deposits are osmiophilic and are present in basal lamina beneath the endothelium, as well as admixed with the adjacent connective tissue (arrows). The aggregates are of no particular shape or size, and they are not present within endothelium cells or within the vascular lumen. Bar indicates 1 μm.

athy involving arterioles, capillaries, and venules. The vasculopathy was characterized on light and electron microscopy by three main features: (1) thickening of the vascular media by a disorganized mixture of collagen, elastin fragments, basement membrane, lysosomes, and granular electron-dense material or lipid that had replaced the medial smooth-muscle cells; (2) perivascular cells, of uncertain identity, containing multiple large complex lysosomes and lipid within their cytoplasm; and (3) swollen astrocytic foot processes surrounding the involved vessels. These changes were present in all three patients. None of our patients showed any abnormalities of intima. Specifically, there was no evidence of atherosclerosis or vasculitis such as intimal thickening, focal deposition of lipid, lipohyalinosis, or fibrinoid necrosis. There was no evidence of amyloidosis or of a proliferation or deposition of intermediate filaments.

The differential diagnosis in these three patients includes Alzheimer's disease, the most common cause of dementia that may be associated with PHL identified on MRI.[11] Although we cannot completely exclude Alzheimer's disease on the basis of the limited tissue available for pathological examination, the young age of the patients; the lack of prominent aphasia, agnosia, and apraxia despite progressive dementia; the early motor signs; and the presence of the vasculopathy argue strongly against this diagnosis. Another diagnostic possibility is normal pressure hydrocephalus; however, the early onset, the absence of diseases predisposing to meningeal fibrosis, and the asymmetry of motor findings and prominent spasticity in two patients argue against diagnosis. Furthermore, normal pressure hydrocephalus would not explain the pathological findings and the strokelike episodes seen in two of our three patients. Other diseases associated with dementia and PHL identified on MRI that were excluded by clinical, laboratory, or pathological studies include multiple sclerosis, the leukodystrophies, human immunodeficiency virus infection, toluene exposure,[12] and progressive multifocal leukoencephalopathy.

The strokelike episodes and focal motor findings in two of our three patients suggest a vascular origin. None of the patients had cardiac disease or occlusive large-vessel cerebrovascular disease. This suggests that the small-vessel vasculopathy, which was not present in any of our age-matched control patients, was the likely cause of clinical and radiological features in our patients.

Although the clinical and radiological features of our three patients resemble those in patients with BSAE,[1-7] important differences exist. Typically, patients with BSAE are elderly and hypertensive, whereas our patients were middle-aged, and none of them had sustained hypertension. Furthermore, the vascular pathologic features in our patients were different from the vascular changes seen in patients with BSAE, which consist primarily of lipohyalinosis of small arterioles in the deep white matter.[8,9]

There are accumulating epidemiologic and pathologic data to suggest that a large subgroup of PHLs identified on MRI have a vascular origin.[13-15] Risk factors consistently associated with these lesions are old age, hypertension, and ischemic stroke. Pathologically, PHLs are characterized by dilated perivascular spaces surrounding hyalinized, sclerotic, and ectatic vessels; gliosis; and myelin pallor.[13,16,17] Occasionally, areas of cystic infarction are also identified.[18] A commonly proposed theory is that PHLs identified on MRI are caused by subcortical ischemia as a consequence of subcortical occlusive small-vessel disease, perhaps in association with low cerebral blood flow.[13-15] If this theory is true, it is likely that several etiologic subtypes of small-vessel disease may cause these lesions. Indeed, periventricular lesions have been described in patients with poorly controlled hypertension,[14] amyloid angiopathy,[19,20] and mitochondrial angiopathy.[21-24]

The cause of the vasculopathy remains unclear. The complex lysosomes seen in the vessel walls in our patients have been previously described[25] as the result of intoxication with a variety of drugs, but a history of drug abuse was only elicited in one of our patients. No common therapeutic drug was used by all three patients. The electron-dense material seen in the vessel walls is not amyloid, immunoglobulin, intermediate filament, or a glycoprotein. However, the fact that the granular material was identified on the endothelial side of the basal lamina beneath intact endothelial cells and junctions suggests the possibility that this material was transported from the vascular lumen.

Further studies are necessary to clarify the spectrum of vasculopathies associated with dementia and PHLs identified on MRI.

We thank Denise F. Egleton for the preparation of the manuscript, Cathy Sila, MD, Gene Barnett, MD, Donald Goodkin, MD, and John P. Conomy, MD, for assistance in providing patients' material, and Richard Ransohoff, MD, for his comments on the manuscript.

Tegretol®

carbamazepine USP

200-mg scored tablets
100-mg chewable tablets

...because after seizure control, there's a lot of living to do!

TEGRETOL is indicated for children 6 years and older and adults.

Because of the potential for serious hematologic adverse reactions, it is important that you become thoroughly familiar with the full Prescribing Information for TEGRETOL on the next page, especially the boxed warning.

Chewable Tablets of 100 mg—red-speckled, pink Tablets of 200 mg—pink

WARNING

APLASTIC ANEMIA AND AGRANULOCYTOSIS HAVE BEEN REPORTED IN ASSOCIATION WITH THE USE OF TEGRETOL. DATA FROM A POPULATION-BASED CASE CONTROL STUDY DEMONSTRATE THAT THE RISK OF DEVELOPING THESE REACTIONS IS 5-8 TIMES GREATER THAN IN THE GENERAL POPULATION. HOWEVER, THE OVERALL RISK OF THESE REACTIONS IN THE UNTREATED GENERAL POPULATION IS LOW. APPROXIMATELY SIX PATIENTS PER ONE MILLION POPULATION PER YEAR FOR AGRANULOCYTOSIS AND TWO PATIENTS PER ONE MILLION POPULATION PER YEAR FOR APLASTIC ANEMIA

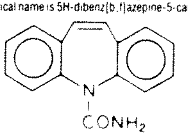
ALTHOUGH REPORTS OF TRANSIENT OR PERSISTENT DECREASED PLATELET OR WHITE BLOOD CELL COUNTS ARE NOT UNCOMMON IN ASSOCIATION WITH THE USE OF TEGRETOL, DATA ARE NOT AVAILABLE TO ESTIMATE ACCURATELY THEIR INCIDENCE OR OUTCOME. HOWEVER, THE VAST MAJORITY OF THE CASES OF LEUKOPENIA HAVE NOT PROGRESSED TO THE MORE SERIOUS CONDITIONS OF APLASTIC ANEMIA OR AGRANULOCYTOSIS

BECAUSE OF THE VERY LOW INCIDENCE OF AGRANULOCYTOSIS AND APLASTIC ANEMIA, THE VAST MAJORITY OF MINOR HEMATOLOGIC CHANGES OBSERVED IN MONITORING OF PATIENTS ON TEGRETOL ARE UNLIKELY TO SIGNAL THE OCCURRENCE OF EITHER ABNORMALITY NONETHELESS. COMPLETE PRETREATMENT HEMATOLOGICAL TESTING SHOULD BE OBTAINED AS A BASELINE. IF A PATIENT IN THE COURSE OF TREATMENT EXHIBITS LOW OR DECREASED WHITE BLOOD CELL OR PLATELET COUNTS, THE PATIENT SHOULD BE MONITORED CLOSELY. DISCONTINUATION OF THE DRUG SHOULD BE CONSIDERED IF ANY EVIDENCE OF SIGNIFICANT BONE MARROW DEPRESSION DEVELOPS

Before prescribing Tegretol, the physician should be thoroughly familiar with the details of this prescribing information, particularly regarding use with other drugs, especially those which accentuate toxicity potential.

DESCRIPTION

Tegretol, carbamazepine USP, is an anticonvulsant and specific analgesic for trigeminal neuralgia, available as chewable tablets of 100 mg and tablets of 200 mg for oral administration. Its chemical name is 5H-dibenz[b,f]azepine-5-carboxamide, and its structural formula is



Carbamazepine USP is a white to off-white powder, practically insoluble in water and soluble in alcohol and in acetone. Its molecular weight is 236.27

Inactive Ingredients. Colloidal silicon dioxide, FD&C Red No. 3 (chewable tablets only), FD&C Red No. 40 (200-mg tablets only), flavoring (chewable tablets only), gelatin, glycerin, magnesium stearate, sodium starch glycolate (chewable tablets only), starch, stearic acid, and sucrose (chewable tablets only)

CLINICAL PHARMACOLOGY

In controlled clinical trials, Tegretol has been shown to be effective in the treatment of psychomotor and grand mal seizures, as well as trigeminal neuralgia

It has demonstrated anticonvulsant properties in rats and mice with electrically and chemically induced seizures. It appears to act by reducing polysynaptic responses and blocking the post-tetanic potentiation. Tegretol greatly reduces or abolishes pain induced by stimulation of the infraorbital nerve in cats and rats. It depresses thalamic potential and bulbar and polysynaptic reflexes, including the linguomandibular reflex in cats. Tegretol is chemically unrelated to other anticonvulsants or other drugs used to control the pain of trigeminal neuralgia. The mechanism of action remains unknown

Tegretol tablets are adequately absorbed after oral administration at a slower rate than a solution, thus avoiding undesirably high peak concentrations. Tegretol chewable tablets may produce higher peak levels than the same dose given as regular tablets. Tegretol in blood is 76% bound to plasma proteins. Plasma levels of Tegretol are variable and may range from 0.5-25 µg/ml, with no apparent relationship to the daily intake of the drug. Usual adult therapeutic levels are between 4 and 12 µg/ml. Following oral administration, serum levels peak at 4 to 5 hours. The CSF/serum ratio is 0.22, similar to the 22% unbound Tegretol in serum. Because Tegretol may induce its own metabolism, the half-life is also variable. Initial half-life values range from 25-65 hours, with 12-17 hours on repeated doses. Tegretol is metabolized in the liver. After oral administration of 14C-carbamazepine, 72% of the administered radioactivity was found in the urine and 28% in the feces. This urinary radioactivity was composed largely of hydroxylated and conjugated metabolites, with only 3% of unchanged Tegretol. Transplacental passage of Tegretol is rapid (30 to 60 minutes), and the drug is accumulated in fetal tissues, with higher levels found in liver and kidney than in brain and lungs

INDICATIONS AND USAGE

Epilepsy: Tegretol is indicated for use as an anticonvulsant drug. Evidence supporting efficacy of Tegretol as an anticonvulsant was derived from active drug-controlled studies that enrolled patients with the following seizure types

1 Partial seizures with complex symptomatology (psychomotor, temporal lobe). Patients with these seizures appear to show greater improvement than those with other types

2 Generalized tonic-clonic seizures (grand mal)

3 Mixed seizure patterns which include the above, or other partial or generalized seizures

Absence seizures (petit mal) do not appear to be controlled by Tegretol (see PRECAUTIONS, General)

Trigeminal Neuralgia: Tegretol is indicated in the treatment of the pain associated with true trigeminal neuralgia

Beneficial results have also been reported in glossopharyngeal neuralgia

This drug is not a simple analgesic and should not be used for the relief of trivial aches or pains

CONTRAINDICATIONS

Tegretol should not be used in patients with a history of previous bone marrow depression, hypersensitivity to the drug, or known sensitivity to any of the tricyclic compounds, such as amitriptyline, desipramine, imipramine, protriptyline, nortriptyline, etc. Likewise, on theoretical grounds its use with monoamine oxidase inhibitors is not recommended. Before administration of Tegretol, MAO inhibitors should be discontinued for a minimum of fourteen days, or longer if the clinical situation permits

WARNINGS

Patients with a history of adverse hematologic reaction to any drug may be particularly at risk

Severe dermatologic reactions including toxic epidermal necrolysis (Lyell's syndrome) and Stevens-Johnson syndrome, have been reported with Tegretol. These reactions have been extremely rare. However, a few fatalities have been reported

Tegretol has shown mild anticholinergic activity, therefore, patients with increased intraocular pressure should be closely observed during therapy

Because of the relationship of the drug to other tricyclic compounds, the possibility of activation of a latent psychosis and, in elderly patients, of confusion or agitation should be borne in mind

PRECAUTIONS

General: Before initiating therapy, a detailed history and physical examination should be made

Tegretol should be used with caution in patients with a mixed seizure disorder that includes atypical absence seizures, since in these patients Tegretol has been associated with increased frequency of generalized convulsions (see INDICATIONS AND USAGE)

Therapy should be prescribed only after critical benefit-to-risk appraisal in patients with a history of cardiac, hepatic or renal damage, adverse hematologic reaction to other drugs, or interrupted courses of therapy with Tegretol

Information for Patients: Patients should be made aware of the early toxic signs and symptoms of a potential hematologic problem, such as fever, sore throat, ulcers in the mouth, easy bruising, petechial or purpuric hemorrhage, and should be advised to report to the physician immediately if any such signs or symptoms appear

Since dizziness and drowsiness may occur, patients should be cautioned about the hazards of operating machinery or automobiles or engaging in other potentially dangerous tasks

Laboratory Tests: Complete pretreatment blood counts, including platelets and possibly reticulocytes and serum iron, should be obtained as a baseline. If a patient in the course of treatment exhibits low or decreased white blood cell or platelet counts, the patient should be monitored closely. Discontinuation of the drug should be considered if any evidence of significant bone marrow depression develops

Baseline and periodic evaluations of liver function, particularly in patients with a history of liver disease, must be performed during treatment with this drug since liver damage may occur. The drug should be discontinued immediately in cases of aggravated liver dysfunction or active liver disease

Baseline and periodic eye examinations, including slit-lamp, funduscopy and tonometry, are recommended since many phenothiazines and related drugs have been shown to cause eye changes

Baseline and periodic complete urinalysis and BUN determinations are recommended for patients treated with this agent because of observed renal dysfunction

Monitoring of blood levels (see CLINICAL PHARMACOLOGY) has increased the efficacy and safety of anticonvulsants. This monitoring may be particularly useful in cases of dramatic increase in seizure frequency and for verification of compliance. In addition, measurement of drug serum levels may aid in determining the cause of toxicity when more than one medication is being used

Thyroid function tests have been reported to show decreased values with Tegretol administered alone

Hyponatremia has been reported in association with Tegretol use, either alone or in combination with other drugs

Drug Interactions: The simultaneous administration of phenobarbital, phenytoin, or primidone, or a combination of two, produces a marked lowering of serum levels of Tegretol. The effect of valproic acid on Tegretol blood levels is not clearly established, although an increase in the ratio of active 10, 11-epoxide metabolite to parent compound is a consistent finding

The half-lives of phenytoin, warfarin, doxycycline, and theophylline were significantly shortened when administered concurrently with Tegretol. Haloperidol and valproic acid serum levels may be reduced when these drugs are administered with Tegretol. The doses of these drugs may therefore have to be increased when Tegretol is added to the therapeutic regimen

Concomitant administration of Tegretol with erythromycin, cimetidine, propoxyphene, isoniazid or calcium channel blockers has been reported to result in elevated plasma levels of carbamazepine resulting in toxicity in some cases. Also, concomitant administration of carbamazepine and lithium may increase the risk of neurotoxic side effects

Alterations of thyroid function have been reported in combination therapy with other anticonvulsant medications

Breakthrough bleeding has been reported among patients receiving concomitant oral contraceptives and their reliability may be adversely affected

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carbamazepine, when administered to Sprague-Dawley rats for two years in the diet at doses of 25, 75, and 250 mg/kg/day, resulted in a dose-related increase in the incidence of hepatocellular tumors in females and of benign interstitial cell adenomas in the testes of males

Carbamazepine must, therefore, be considered to be carcinogenic in Sprague-Dawley rats. Bacterial and mammalian mutagenicity studies using carbamazepine produced negative results. The significance of these findings relative to the use of carbamazepine in humans is, at present, unknown

Pregnancy Category C: Tegretol has been shown to have adverse effects in reproduction studies in rats when given orally in dosages 10-25 times the maximum human daily dosage of 1200 mg. In rat teratology studies, 2 of 135 offspring showed kinked ribs at 250 mg/kg and 4 of 119 offspring at 650 mg/kg showed other anomalies (cleft palate, 1, talipes, 1, anophthalmos, 2). In reproduction studies in rats, nursing offspring demonstrated a lack of weight gain and an unkempt appearance at a maternal dosage level of 200 mg/kg

There are no adequate and well-controlled studies in pregnant women. Epidemiological data suggest that there may be an association between the use of carbamazepine during pregnancy and congenital malformations, including spina bifida. Tegretol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus

Retrospective case reviews suggest that, compared with monotherapy, there may be a higher prevalence of teratogenic effects associated with the use of anticonvulsants in combination therapy. Therefore, monotherapy is recommended for pregnant women

It is important to note that anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus

Labor and Delivery: The effect of Tegretol on human labor and delivery is unknown

Nursing Mothers: During lactation, concentration of Tegretol in milk is approximately 60% of the maternal plasma concentration

Because of the potential for serious adverse reactions in nursing infants from carbamazepine, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established

ADVERSE REACTIONS

If adverse reactions are of such severity that the drug must be discontinued, the physician must be aware that abrupt discontinuation of any anticonvulsant drug in a responsive epileptic patient may lead to seizures or even status epilepticus with its life-threatening hazards

The most severe adverse reactions have been observed in the hemopoietic system (see boxed WARNING), the skin and the cardiovascular system

The most frequently observed adverse reactions, particularly during the initial phases of therapy, are dizziness, drowsiness, unsteadiness, nausea, and vomiting. To minimize the possibility of such reactions, therapy should be initiated at the low dosage recommended

The following additional adverse reactions have been reported

Hemopoietic System. Aplastic anemia, agranulocytosis, pancytopenia, bone marrow depression, thrombocytopenia, leukopenia, leukocytosis, eosinophilia, acute intermittent porphyria

Skin. Pruritic and erythematous rashes, urticaria, toxic epidermal necrolysis (Lyell's syndrome) (see WARNINGS), Stevens-Johnson syndrome (see WARNINGS), photosensitivity reactions, alterations in skin pigmentation, exfoliative dermatitis, erythema multiforme and nodosum, purpura, aggravation of disseminated lupus erythematosus, alopecia, and diaphoresis. In certain cases, discontinuation of therapy may be necessary

Cardiovascular System. Congestive heart failure, edema, aggravation of hypertension, hypotension, syncope and collapse, aggravation of coronary artery disease, arrhythmias and AV block, primary thrombophlebitis, recurrence of thrombophlebitis, and adenopathy or lymphadenopathy

Some of these cardiovascular complications have resulted in fatalities. Myocardial infarction has been associated with other tricyclic compounds

Liver. Abnormalities in liver function tests, cholestatic and hepatocellular jaundice, hepatitis

Respiratory System. Pulmonary hypersensitivity characterized by fever, dyspnea, pneumonitis or pneumonia

Genitourinary System. Urinary frequency, acute urinary retention, oliguria with elevated blood pressure, azotemia, renal failure, and impotence. Albuminuria, glycosuria, elevated BUN and microscopic deposits in the urine have also been reported

Testicular atrophy occurred in rats receiving Tegretol orally from 4 to 52 weeks at dosage levels of 50 to 400 mg/kg/day. Additionally, rats receiving Tegretol in the diet for two years at dosage levels of 25, 75, and 250 mg/kg/day had a dose-related incidence of testicular atrophy and aspermatogenesis. In dogs, it produced a brownish discoloration, presumably a metabolite, in the urinary bladder at dosage levels of 50 mg/kg and higher. Relevance of these findings to humans is unknown

Nervous System. Dizziness, drowsiness, disturbances of coordination, confusion, headache, fatigue, blurred vision, visual hallucinations, transient diplopia, oculomotor disturbances, nystagmus, speech disturbances, abnormal involuntary movements, peripheral neuritis and paresthesias, depression with agitation, talkativeness, tinnitus, and hyperacusis

There have been reports of associated paralysis and other symptoms of cerebral arterial insufficiency, but the exact relationship of these reactions to the drug has not been established

Digestive System. Nausea, vomiting, gastric distress and abdominal pain, diarrhea, constipation, anorexia, and dryness of the mouth and pharynx, including glossitis and stomatitis

Eyes. Scattered, punctate, cortical lens opacities, as well as conjunctivitis have been reported. Although a direct causal relationship has not been established, many phenothiazines and related drugs have been shown to cause eye changes

Musculoskeletal System. Aching joints and muscles, and leg cramps

Metabolism. Fever and chills. Inappropriate antidiuretic hormone (ADH) secretion syndrome has been reported. Cases of frank water intoxication, with decreased serum sodium (hyponatremia) and confusion, have been reported in association with Tegretol use (see PRECAUTIONS, Laboratory Tests)

Other. Isolated cases of a lupus erythematosus-like syndrome have been reported. There have been occasional reports of elevated levels of cholesterol, HDL cholesterol and triglycerides in patients taking anticonvulsants

A case of aseptic meningitis, accompanied by myoclonus and peripheral eosinophilia has been reported in a patient taking carbamazepine in combination with other medications. The patient was successfully dechallenged, and the meningitis reappeared upon rechallenge with carbamazepine

DRUG ABUSE AND DEPENDENCE

No evidence of abuse potential has been associated with Tegretol, nor is there evidence of psychological or physical dependence in humans

OVERDOSAGE

Acute Toxicity

Lowest known lethal dose: adults, >60 g (39-year-old man). Highest known doses survived: adults, 30 g (31-year-old woman), children, 10 g (6-year-old boy), small children, 5 g (3-year-old girl)

Oral LD50 in animals (mg/kg): mice, 1100-3750, rats, 3850-4025, rabbits, 1500-2680, guinea pigs, 920

Signs and Symptoms

The first signs and symptoms appear after 1-3 hours. Neuromuscular disturbances are the most prominent. Cardiovascular disorders are generally milder, and severe cardiac complications occur only when very high doses (>60 g) have been ingested

Respiration. Irregular breathing, respiratory depression

Cardiovascular System. Tachycardia, hypotension or hypertension, shock, conduction disorders

Nervous System and Muscles. Impairment of consciousness ranging in severity to deep coma. Convulsions, especially in small children. Motor restlessness, muscular twitching, tremor, athetoid movements, opisthotonos, ataxia, drowsiness, dizziness, mydriasis, nystagmus, adiadochokinesia, ballism, psychomotor disturbances, dysmetria. Initial hyperreflexia, followed by hyporeflexia

Gastrointestinal Tract. Nausea, vomiting

Kidneys and Bladder. Anuria or oliguria, urinary retention

Laboratory Findings. Isolated instances of overdosage have included leukocytosis, reduced leukocyte count, glycosuria and acetonuria. EEG may show dysrhythmias

Combined Poisoning. When alcohol, tricyclic antidepressants, barbiturates or hydantoins are taken at the same time, the signs and symptoms of acute poisoning with Tegretol may be aggravated or modified

Treatment

The prognosis in cases of severe poisoning is critically dependent upon prompt elimination of the drug, which may be achieved by inducing vomiting, irrigating the stomach, and by taking appropriate steps to diminish absorption. If these measures cannot be implemented without risk on the spot, the patient should be transferred at once to a hospital, while ensuring that vital functions are safeguarded. There is no specific antidote

Elimination of the Drug. Induction of vomiting

Gastric lavage. Even when more than 4 hours have elapsed following ingestion of the drug, the stomach should be repeatedly irrigated, especially if the patient has also consumed alcohol

Measures to Reduce Absorption. Activated charcoal, laxatives

Measures to Accelerate Elimination. Forced diuresis

Dialysis is indicated only in severe poisoning associated with renal failure. Replacement transfusion is indicated in severe poisoning in small children

Respiratory Depression. Keep the airways free, resort, if necessary, to endotracheal intubation, artificial respiration, and administration of oxygen

Hypotension, Shock. Keep the patient's legs raised and administer a plasma expander. If blood pressure fails to rise despite measures taken to increase plasma volume, use of vasoactive substances should be considered

Convulsions. Diazepam or barbiturates

Warning. Diazepam or barbiturates may aggravate respiratory depression (especially in children), hypotension, and coma. However, barbiturates should not be used if drugs that inhibit monoamine oxidase have also been taken by the patient either in overdosage or in recent therapy (within one week)

Surveillance. Respiration, cardiac function (ECG monitoring), blood pressure, body temperature, pupillary reflexes, and kidney and bladder function should be monitored for several days

Treatment of Blood Count Abnormalities. If evidence of significant bone marrow depression develops, the following recommendations are suggested: (1) stop the drug, (2) perform daily CBC, platelet and reticulocyte counts, (3) do a bone marrow aspiration and trephine biopsy immediately and repeat with sufficient frequency to monitor recovery

Special periodic studies might be helpful as follows: (1) white cell and platelet antibodies, (2) 59Fe—ferrokinetic studies, (3) peripheral blood cell typing, (4) cytogenetic studies on marrow and peripheral blood, (5) bone marrow culture studies for colony-forming units, (6) hemoglobin electrophoresis for A_2 and F hemoglobin, and (7) serum folic acid and B_{12} levels

A fully developed aplastic anemia will require appropriate, intensive monitoring and therapy, for which specialized consultation should be sought

DOSAGE AND ADMINISTRATION

Monitoring of blood levels has increased the efficacy and safety of anticonvulsants (see PRECAUTIONS, Laboratory Tests). Dosage should be adjusted to the needs of the individual patient. A low initial daily dosage with a gradual increase is advised. As soon as adequate control is achieved, the dosage may be reduced very gradually to the minimum effective level. Tablets should be taken with meals

Epilepsy (see INDICATIONS AND USAGE)

Adults and children over 12 years of age—Initial: 200 mg b.i.d. Increase at weekly intervals by adding up to 200 mg per day using a t.i.d. or q.i.d. regimen until the best response is obtained. Dosage should generally not exceed 1000 mg daily in children 12 to 15 years of age, and 1200 mg daily in patients above 15 years of age. Doses up to 1600 mg daily have been used in adults in rare instances. ***Maintenance***: Adjust dosage to the minimum effective level, usually 800-1200 mg daily

Children 6-12 years of age—Initial: 100 mg b.i.d. Increase at weekly intervals by adding 100 mg per day using a t.i.d. or q.i.d. regimen until the best response is obtained. Dosage should generally not exceed 1000 mg. ***Maintenance***: Adjust dosage to the minimum effective level, usually 400-800 mg daily

Combination Therapy: Tegretol may be used alone or with other anticonvulsants. When added to existing anticonvulsant therapy, the drug should be added gradually while the other anticonvulsants are maintained or gradually decreased, except phenytoin, which may have to be increased (see PRECAUTIONS, Drug Interactions and Pregnancy Category C)

Trigeminal Neuralgia (see INDICATIONS AND USAGE)

Initial: 100 mg b.i.d. on the first day for a total daily dose of 200 mg. This daily dose may be increased by up to 200 mg a day using increments of 100 mg every 12 hours only as needed to achieve freedom from pain. Do not exceed 1200 mg daily

Maintenance: Control of pain can be maintained in most patients with 400 mg to 800 mg daily. However, some patients may be maintained on as little as 200 mg daily, while others may require as much as 1200 mg daily. At least once every 3 months throughout the treatment period, attempts should be made to reduce the dose to the minimum effective level or even to discontinue the drug

HOW SUPPLIED

Chewable Tablets 100 mg—round, red-speckled, pink, single-scored (imprinted Tegretol on one side and 52 twice on the scored side)

Bottles of 100	NDC 0028-0052-01
Unit Dose (blister pack)	
Box of 100	
(strips of 10)	NDC 0028-0052-61

Tablets 200 mg—capsule-shaped, pink, single-scored (imprinted Tegretol on one side and 27 twice on the scored side)

Bottles of 100	NDC 0028-0027-01
Bottles of 1000	NDC 0028-0027-10
Gy-Pak®—One Unit	
12 bottles—100 tablets each	NDC 0028-0027-65
Unit Dose (blister pack)	
Box of 100	
(strips of 10)	NDC 0028-0027-61

Samples, when available, are identified by the word *SAMPLE* appearing on each tablet

Protect from moisture

Dispense in tight container (USP)

Also available as: Tegretol suspension 100 mg/5 ml, in 450 ml bottles

Regional Cerebral Blood Flow Correlates of Language Processes in Reading Disability

D. Lynn Flowers, PhD; Frank B. Wood, PhD; Cecile E. Naylor, PhD

• **This series of studies tests the hypothesis of abnormal left hemisphere activation in reading-disabled subjects during language task performance. First, a left superotemporal focus of activation, as measured by regional cerebral blood flow, was found to be positively correlated with task accuracy in a group of 69 normal adults. Next, that left superotemporal activation was replicated in a second group of 83 adults whose childhood reading ability was known from standardized tests given in childhood. Finally, in that latter group, childhood reading ability was also found to be inversely correlated with focal activation in a more posterior, temporoparietal area of cortex. Adult reading outcome was statistically unrelated to this finding. The results are interpreted as suggesting a trait anomaly of left hemisphere cerebral activation in adults who were dyslexic as children and as providing an existence proof of individual differences in focal cortical activation sites during constant task demands.**

(*Arch Neurol.* 1991;48:637-643)

Dyslexia or reading disability, defined as the failure to achieve age-predicted reading levels despite normal intelligence and adequate learning opportunity, has triggered numerous theoretical explanations. However, inasmuch as persistent language deficits are consistently found,[1-4] a left hemisphere neural anatomical substrate has been proposed especially often for developmental reading disability.[5]

Chronic atypical left hemisphere organization in dyslexic individuals is suggested by two types of anatomical evidence. First, at the microscopic level, neuronal anomalies including dysplasias in the cortical layers and ectopic neuronal cell bodies have been observed in human dyslexics. In contrast with findings in normal readers, consecutively presenting dyslexic patients were all found by Galaburda and others[6-8] to have neural anomalies, predominantly in the left perisylvian cortex. These abnormalities are proposed to occur in the second trimester during the wave of cell migration that forms the upper cortical layers. Similar anomalies can be induced in laboratory animals by creating small necroses in the cortex, thus interrupting cells as they migrate into the superficial cortical layers.[9] In humans, a specific necrotic agent has not been identified, but a slower maturation rate of the left hemisphere temporal region is proposed to render it especially vulnerable to insult during this period of migration.[5]

Second, at the macroscopic level, atypical neural organization in reading-disabled subjects is suggested by the absence of the normal left-greater-than-right asymmetry in the posterotemporal planum in autopsy material.[6,7] Studies using in vivo techniques, computed tomography, and magnetic resonance imaging also have reported temporal planum symmetry or reversed asymmetry statistically more often in language-disabled subjects.[10,11] A possible origin is anomalous cell migration and organization, demonstrated experimentally in primate studies[12,13]: in the fetal monkey, after a unilateral frontal lesion, greater-than-normal neural projections are found bilaterally. The responsible mechanism is believed to be reduced cell death during corticogenesis. In the case of reading disability, the more symmetrical temporal planum might then also result from an original unilateral lesion, possibly in the left hemisphere.

Thus, there is reason, from microstructural and gross structural studies, to consider that the behavioral deficit observed in developmental reading disability may be related to the anomalous organization of tissue lying within the left hemisphere processing regions.

In addition, physiological evidence suggests that verbal processing deficits are related to atypical neural activity. The intraoperative brain stimulation mapping technique has shown that sites functionally involved with basic language skills (for instance, naming, orofacial sequencing, and phonetic discrimination) are distributed along the sylvian fissure.[14,15] In a group of epileptic patients with left hemisphere dominance for language, greater variability in the distribution of language functions was reported than would be predicted by the classic models. The extent of epileptogenic tissue did not predict this variability, but verbal ability did. That is, patients with poorer verbal ability demonstrated more naming interruptions in response to inferoparietal (angular gyrus) stimulation, a significant posterior shift from the left temporal site that was activated in patients with higher verbal ability.

Based on these findings, Ojemann and Whitaker[16] have speculated that displaced representation of a core language function from the posterotemporal area into the nearby parietal region might be typical of those with poorer verbal ability. They have ob-

served that early left anterotemporal lesions result in wider representation of naming in the posterotemporal and parietal cortex. Functional displacement of some temporal lobe language mechanisms to the surrounding parietal cortex, the extent of which is related to how much the lesion encroaches on language centers, also has been proposed by Rasmussen and Milner[17] to occur postnatally following early brain insult. Translocalization of function into nearby cortical areas following experimental lesions is also known to occur in young, nonhuman primates.[18,19]

Table 1.—Descriptive Measures for 69 Normal Subjects*

Variable	Mean ± SD	Range
Age, y	29.8 ± 7.5	18-46
Education, y	14.9 ± 2.2	12-25
Task accuracy (d′)	4.8 ± 1.1	1.9-6.0
Anxiety score	56.3 ± 11.3	40-91
Estimated Full-Scale IQ	108.6 ± 12.0	92-146
Estimated Verbal IQ	107.1 ± 13.2	88-150
Estimated Performance IQ	108.7 ± 11.2	87-139

*Anxiety Score is the sum of the pretest and posttest scores on the Spielberger State-Trait Anxiety Inventory (n = 47). Estimated IQ scores are extrapolated from two Verbal subscales (Vocabulary and Digit Span) and two Performance subscales (Block Design and Digit Symbol) of the Wechsler Adult Intelligence Scale-Revised.

Table 2.—Descriptive Measures for 83 Orton Group Subjects by Childhood Reading Level*

	Reading Disabled (n = 33)	Borderline (n = 27)	Nondisabled (n = 23)

†Reading-disabled subjects differ from all others by Tukey's Studentized Range Test at $P < .05$.

‡All paired comparisons are significantly different.

§Nondisabled readers do not differ significantly from subjects in the normal (study 1) group.

‖Reading-disabled and borderline subjects differ from good readers.

PHYSIOLOGICAL MEASUREMENTS

Of the noninvasive physiological measures available for study of nonclinical subjects, the xenon 133 regional cerebral blood flow (rCBF) method is well suited for monitoring the neural correlates of sustained language functions. Its temporal window is on the order of a few minutes, its relative safety and low cost allow the use of large normal reference groups and multiple conditions,[20,21] and its ability to resolve gray- vs white-matter flow exceeds that of other methods.

Only two rCBF studies of dyslexic adults have been published to date. The first[22] compared two severely impaired male subjects with age-matched male subjects of normal reading ability while they read a prose story silently. A second study[23] compared a group of 14 dyslexic male subjects with normal subjects on a semantic classification task. Neither study concluded that dyslexic subjects had a left hemisphere verbal processing deficit. Definitive conclusions cannot be drawn from these studies, however: the sample sizes were too small to control statistically for trait and state individual differences due to age, IQ, and anxiety; and activation tasks were not closely related to those particular language mechanisms involved in reading disability.

In this study, an orthographic task was used, since persisting spelling deficit is often found to characterize adults with reading disability histories, even when their oral reading has improved.[24]

Clearly, it is also desirable to study a large sample of adults whose childhood reading and academic histories are fully documented. Such a population was available for this investigation. The great advantage of using this population was that the diagnosis of reading disability could be made based solely on objective childhood reading tests, which could then be used to predict adult blood flow patterns elicited by cognitive tasks. Thus, regardless of adult accomplishment due to training or practice, a hypothesis of neural physiological deficiency rooted in early development could be tested in subjects defined by their documented childhood reading disability.

THEORETICAL PREDICTIONS

From the studies of Ojemann and coworkers and related evidence, it was plausible to predict that (1) in a normal, nonclinical population, a language-based task would be accompanied by focal activation of the left hemisphere perisylvian (superotemporal) regions; and (2) in an adult population that included subjects with documented childhood reading impairment, displacement or spread of activation to surrounding regions, in particular to the adjacent posterior (temporoparietal) region, would be related statistically to the degree of early disability.

Three studies utilizing the rCBF method are reported herein. The first involves orthographic task accuracy correlation with blood flow during the task in healthy adults with no history of reading problems; the second replicates the same correlation in a group of adults with documented, varied reading histories; and the third is a prediction from childhood reading level of adult blood flow as measured during task activation.

SUBJECTS AND METHODS

Subjects

The three studies reported shared the same equipment, stimuli, and procedure but utilized different sets of subjects. Experimental procedures and safety factors were explained to subjects and informed consent was obtained.

For study 1, a normal sample of 69 subjects (39 men and 30 women) performed an orthographic analysis task. All subjects were right-handed and of average intelligence (Wechsler Adult Intelligence Scale–Revised[25]; Table 1). An interview determined that no subject had a history of reading remediation or had repeated grades.

The 83 subjects (72 men and 11 women) in studies 2 and 3 were referred to the Orton Reading Center in Winston-Salem, NC, during its operation between 1957 and 1972. Their childhood records, accessed with written permission, are maintained at the Health Sciences Library of Columbia University, New York, NY. These records contain detailed parent and teacher interviews, school reports, and scores on standardized reading, achievement, and IQ tests. Variables used to control statistically for subject differences are given in Table 2.

Childhood and adult intellectual ability was assessed using standardized tests appropriate to the age range.[25,26] All subjects had childhood and adult IQ scores of at least 80 on either the Verbal or the Performance scale.

Subjects who had attended the Orton Reading Center were assigned to reading levels based on childhood reading ability using the Reading Quotient (RQ) according to the following formula:[27] RQ = (Reading Age/Chronological Age) × 100. "Reading age" is defined as the reading grade level plus 5, determined by an oral reading test (either the Gray Oral Reading Test[28] or the reading portion of the Wide Range Achievement Test [WRAT][29]). If both of the two oral reading quotients were 82 or less, a subject was said to be reading disabled (n = 33). If both quotients were above 91, then the subject was classified as not reading disabled (n = 23). All those not meeting these stringent criteria were classified as borderline (n = 27). The cutoff scores were chosen to represent local school guidelines for learning-disabled classification when recruited, ie, a diagnosis of reading disability is equivalent to being at least 1.5 years behind the reading grade level at the beginning of the third grade.

For the Orton Reading Center group, two criteria defined current (adult) reading level: scores on the WRAT-Revised (WRAT-R)[30] and a reading discrepancy score (difference between the actual reading level on the Gray Oral Reading Test and the expected reading level as calculated using the formula of Finucci et al[31]). Cutoff scores of 82 and 91 on the WRAT-R and −1.2 and −0.6 discrepancy on the Gray scores were set.

All subjects were free of known neurological impairment, major psychopathological conditions, hearing or other sensory impairment, and chronic pulmonary dysfunction. Handedness in the Orton Reading Center group was assessed by a self-report inventory.[32] Seven were left-handed and six were ambidextrous.

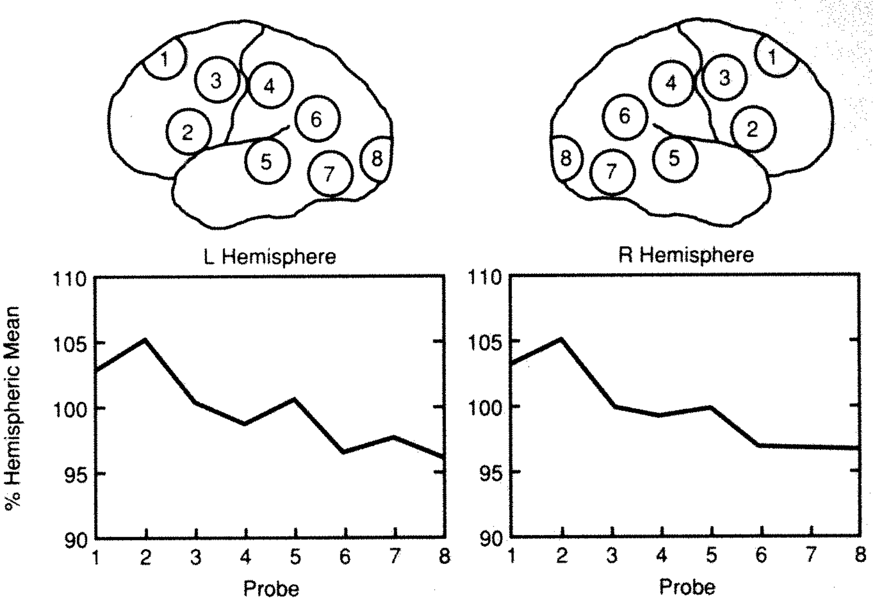

Fig 1.—Hemispheric mean corrected values as a function site for 69 normal subjects. Probe locations: 1, frontal eye fields; 2, Broca's area; 3, hand motor; 4, hand sensory; 5, Wernicke's area; 6, temporoparietal area; 7, inferior temporo-occipital; and 8, primary occipital.

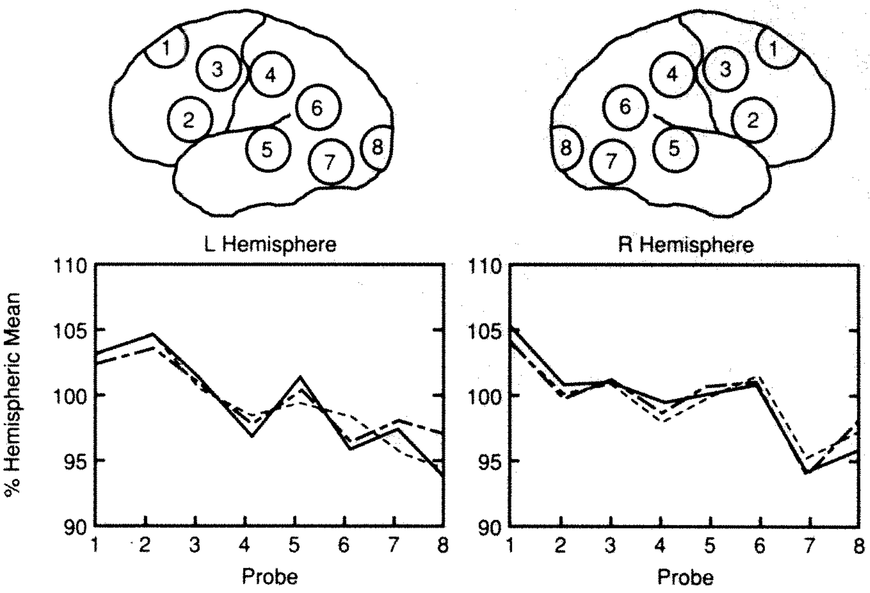

Fig 2.—Hemispheric mean corrected values plotted as a function of probe sites in the left and right hemispheres of 83 subjects from the Orton Reading Center subject pool by childhood reading classification. Dotted line indicates reading disabled (n = 33); dashed-and-dotted line, borderline (n = 27); and solid line, not reading disabled (n = 23). Probe locations are as in Fig 1.

Equipment

Regional cerebral blood flow was measured by a Novo Cerebrograph 32C system (Novo Diagnostic Systems, Bagsvaerd, Denmark), which dispensed the radioactive tracer (^{133}Xe), collected expired air, and measured gamma emissions from the head in 5-second bins. A minicomputer (PDP-11, Digital Equipment Corp, Maynard, Mass) gave a continual on-line numeric and graphics display of the technical quality of ongoing measurements. Signals warned of carbon dioxide and oxygen level abnormalities. A highly sensitive leak detector monitored leakage from the face mask; a soft plastic device fitted over the subject's nose and mouth to collect expired air. The subject was allowed to adapt and breathe normally.

For each measurement, a mixture of air and concentrated ^{133}Xe (approximately 25.9×10^4 Bq/L of air) was administered for 1 minute while clearance was measured by 16 thallium-activated sodium iodide crystal scintillation detectors mounted in shielded lead collimators, eight on each hemisphere. Sites were chosen to represent primary sensory areas, language regions, and frontal regions thought to be involved in attentional processes. Correct placement of the detectors was assured by matching markers on the helmet to anatomical landmarks. This method had been previously verified using both roentgenogram and cadaver checks.[33]

The Initial Slope Index (ISI) of Risberg et al,[34] a conservative index of gray-matter activity, represents the flow at each probe site. A value for each probe site is calculated from the clearance rate of radioactive tracer at each probe site, beginning when saturation has declined to 20% of its maximum level and continuing over the next minute. The balance of time to the end of the 11-minute measurement period serves to calculate corrections for clearance from nonneural tissue.

Procedures

Subjects performed three tasks, appropriately counterbalanced, involving verbal memory, auditory perception, or spelling analysis. Only results from the spelling task are reported herein.

With the room quiet and darkened, task and tracer delivery were begun simultaneously. Subjects listened to 88 highly imageable, common concrete nouns taken from a standard list[35] and delivered binaurally through ear insert phones (Lanier Worldwide, Atlanta, Ga) via a Dolby cassette recording played on a receiver (Realistic SCR-2500, Tandy Corp, Fort Worth, Tex). Half of the words were exactly four letters long, and these were randomly distributed in the list. The words were delivered at 2.5-second intervals, the entire task taking 3 minutes 40 seconds. Subjects were instructed to make a bimanual finger-lift response to any four-letter word. Hits and false alarms were recorded. Twenty minutes was allowed between tasks.

RESULTS

Following common rCBF practice, each of the 16 ISI values obtained from each subject was corrected by that subject's hemispheric mean flow: (ISI/Mean Flow) × 100. A general linear model related these hemisphere-corrected ISIs either to accuracy of task performance or to childhood reading level. Childhood IQ was included in the model as a covariate to assure that predicted differences in flow were not due to differences in general ability. Also, since the rCBF literature has consistently shown the independent effects of age, gender, and task order on blood flow,[36-39] these variables were entered as covariates in the general linear model predicting flow from task accuracy. Although all 16 probe values could be subjected to post hoc statistical analysis, the hypothesis that perisylvian language areas would be activated by task identifies two a priori sites: the inferior posterofrontal premotor area of Broca (probe 2) and the superior posterotemporal area of Wernicke (probe 5).

Task accuracy was calculated as d', to reflect both hits and false alarms.[40] Mean (±) d' values for the normal and Orton Reading Center groups were 4.8 ± 1.1 and 3.8 ± 1.2, respectively, indicating that the target stimuli were generally well discriminated by all subjects.

Study 1

The rCBF profile of hemisphere corrected ISI values for the 69 normal subjects, plotted by hemisphere and probe sites, is shown in Fig 1. By inspection, the pattern of activation is one of "hyperfrontality" typically seen in normal, comfortably alert subjects,[41] ie, a generally symmetrical profile with greater activation in the frontal as compared with posterior areas. The left temporal site also was somewhat elevated above its neighbors during this auditory verbal task.

Accuracy of task performance was positively correlated with blood flow only at the left Wernicke's area (probe site 5; F[1,63]=4.14, $df=1,63$, $P<.05$) but not at the left Broca's area (probe site 2; $P>.10$) or at any other probe site. The general linear model analyses statistically controlled for differences in flow that might be accounted for by a subject's age, full-scale IQ score, gender, or the influence of task order (ie, whether the task was first, second, or third in a series); none of these variables were confounded with the significant effect in Wernicke's area. In a subset of 47 subjects who completed subjective inventories of state anxiety,[42] statistical control for state anxiety also did not change these relationships.

Therefore, the hypothesis was confirmed for the temporal lobe site: in this normal subject group, accuracy on a spelling-related task was related to focal activation of one left perisylvian region, Wernicke's area. While this finding does not specify which features of accurate task performance evoked the Wernicke's area response, it is apparent that some readily measurable trait and state correlates of task performance, such as IQ and anxiety, were not responsible for the temporal lobe activation.

Study 2

Regional cerebral blood flow values at all probe sites were evaluated but, based on the findings from the normal subject group, it was hypothesized a priori that task d' would predict activation only at the left Wernicke's area (probe 5). Indeed, task performance did predict the rCBF measure at Wernicke's area (F[1,77]=7.22, $P<.01$). In addition to age, IQ, gender, and task order, already statistically accounted for in the analysis, self-reported educational attainment, state anxiety, or handedness as controlling variables also did not change the relationship. Thus, the hypothesized relationship between neural activation of the posterior left hemisphere language area and performance of a spelling task, found first in a normally presenting, nonclinical population, was strongly replicated in a second group of subjects whose childhood reading ability ranged from severely impaired to normal. Task performance was not related to flow at any other site.

Study 3

The rCBF profiles for the Orton Reading Center subjects, plotted by childhood reading level, are shown in Fig 2. The poor readers exhibited a reduced response in Wernicke's area, compared with good readers. That is not surprising, since poor readers performed the task less well, and task performance was shown in study 2 to correlate with Wernicke's area flow.

The hypothesis was that in a group of adults with varied, documented reading histories, the poorer the childhood reading level was, the more likely it was that task-related cortical activation would be accompanied by activation elsewhere than in the temporal lobe language-processing areas. Specifically, given the findings from brain stimulation studies, for this task already shown to be related to activation at Wernicke's area (probe 5), a low childhood reading level would be accompanied by evidence of a shift of activation to the nearby temporoparietal region (probe 6). Since childhood abilities were the basis for reading class assignment, childhood verbal and performance IQ scores were statistically controlled when relating task-induced cortical activation to early reading ability.

In the test for the possible shift toward a more posterior focus of activation, a negative linear relationship was found between childhood reading level and flow at probe site 6 (F[2,75]=3.84, $P<.03$ in the general linear model), the temporoparietal probe site immediately posterior to Wernicke's area. Paired comparisons showed the significant differences to be between good and poor readers ($P<.01$) as well as between borderline and poor readers ($P<.01$). In addition, age, gender, state anxiety, and task order did not account for the relationship. That is, while performing this spelling task, good childhood readers were more likely to reduce (or not to activate) flow at the temporoparietal region, while poor childhood readers were more likely to increase (or not to reduce) activation at that region. A positive relationship between blood flow at Wernicke's area (probe 5) and childhood reading was found to be significant only for the comparison between good and poor readers (F[1,75]=4.30, $P<.05$; Table 3).

Of special importance for the issue of displaced function is the fact that the above inverse relationship between childhood reading and temporoparietal activity is independent of task performance: even when accuracy of task performance is entered into the general linear model, the relationship holds strong (F[2,74]=4.60, $P<.02$). By contrast, the difference in flow at Wernicke's area between extreme childhood reading levels is completely eliminated when differences due to task performance are considered, indicating the tight cou-

Table 3.—Task Performance and Childhood Reading Level Predictions of Blood Flow at Two Left Hemisphere Probe Sites for 83 Orton Subjects*

Predictor Variable	Wernicke's Area (Probe 5) F	Wernicke's Area (Probe 5) *P*	Temporoparietal Area (Probe 6) F	Temporoparietal Area (Probe 6) *P*
Task accuracy (*df* = 1,77)	7.22	<.01	0.87	>.35

*After taking into account variance due to age, gender, task order, and IQ. The IQ scores were the Wechsler Adult Intelligence Scale-Revised Full-Scale score for the adult behavioral measure (task accuracy) and the Wechsler Intelligence Scale for Children Verbal and Performance scores for childhood reading classification. Since adult IQ is used in calculating the adult reading discrepancy score on which adult reading level is based, only childhood IQ was a covariate in adult outcome paired comparisons. RD indicates reading disabled (n = 33); BL, borderline (n = 27); NRD, not reading disabled (n = 23); PRD, persisting reading disabled (n = 18); IRD, improved reading disabled (n = 15); and NI, never impaired (n = 23).

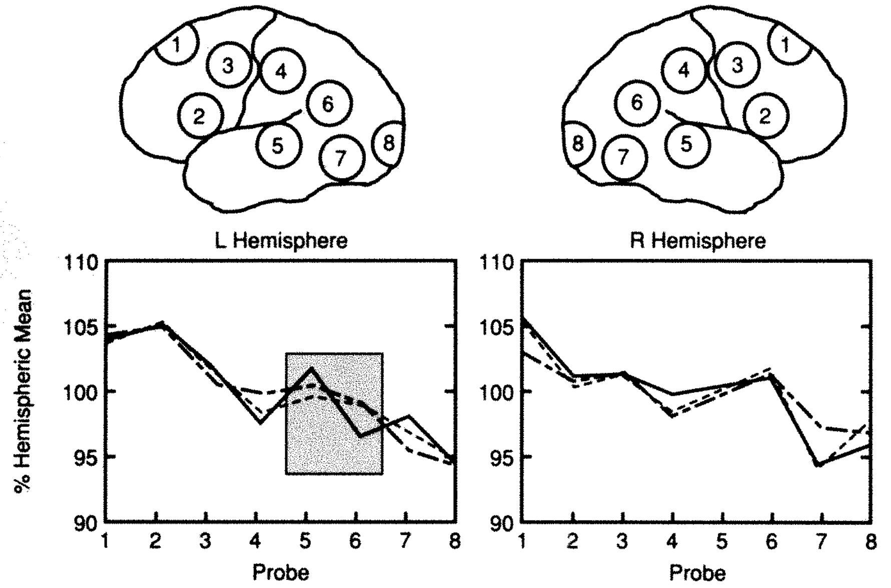

Fig 3.—Hemispheric mean corrected values plotted as a function of adult reading outcome for 56 subjects from the Orton Reading Center subject pool by adult reading outcome. Dotted line indicates persisting reading disabled (n = 18); dashed line, improved reading disabled (n = 15); and solid line, never impaired (n = 23). Probe locations are as in Fig 1.

pling between childhood reading ability and task accuracy in predicting activity specific to that site.

The high temporoparietal flow that characterized poor childhood readers was independent of the adult reading outcome of the poor childhood readers, classified according to the same two oral reading tests used to assign subjects to a childhood reading level. That is, of those who were impaired readers in childhood, the "persisting" and the "improved" subjects had the same Wernicke's area–temporoparietal rCBF profiles (Fig 3). The relationship of childhood reading level to adult blood flow in the temporoparietal region is, therefore, not simply an inverse of that found in Wernicke's area, since the temporoparietal finding is unrelated to task accuracy or to the adult reading outcome of poor childhood readers.

A visual comparison between the blood flow profile of the normal reference group (Fig 1) and the profiles of the Orton Reading Center group, plotted by reading level (Fig 2), suggests differences in the hemisphere-corrected ISIs at probes 2 and 6 in the right hemisphere. A post hoc analysis confirms that the combined Orton Reading Center group as a whole has significantly higher flow than the normal reference group at probes 2 and 6. However, the degree of activation at either probe site is unrelated to any measures of adulthood or childhood cognitive function or academic skill. It is not related to any demographic variable (eg, gender, years of education) or measured trait variable. Thus, there is no apparent relevance of these right hemisphere flow phenomena for dyslexia or other cognitive deficit. However, right temporoparietal (probe 6) flow is significantly and positively correlated with state anxiety in the combined Orton Reading Center sample. Since the anxiety scores are significantly greater in the combined Orton Reading Center sample than in the normal reference group, the best explanation for the right temporoparietal finding seems to be anxiety, not direct functional neuroanatomical differences.

COMMENT

In this investigation using the rCBF technique, a large group of normal adults showed task-specific activation of a left hemisphere region corresponding to the classic language area of Wernicke. This result from 69 normal subjects provides support for selective left superior posterotemporal mediation of this reading-related task. The finding was then confirmed in a second, more varied group of 83 adults that included some severely impaired readers. As compared with good readers, poor childhood readers activated the immediately posterior temporoparietal region more when performing this same task.

Several explanations should be considered. Cortical activation differences between dyslexic subjects and others could reflect previous verbal experience. But, in this test of the relationship between childhood reading levels and adult cortical activation, we equate the subjects for educational experience and show that the effect is still present.

Alternatively, if it can be assumed that reading-impaired subjects (who were less accurate) found the spelling task more difficult, then the greater activation of the temporoparietal region could be related to the additional effort exerted by those subjects. In fact, subject ratings of task difficulty were correlated with task performance ($r = .59$, $P < .0001$). However, the relationship between reading impairment and temporoparietal region activation does not change when subjects are equated for task performance. Therefore, effort due to task difficulty seems an insufficient explanation for the relative enhancement of the more posterior region observed in the impaired group.

The observed more posterior activity could have yet another explanation: it could reflect different strategies employed by dyslexic and normal readers. This raises the question why dyslexic subjects as a group would adopt a different strategy to do this task, a natural question for further research. A neural inefficiency hypothesis is still viable, therefore, since one logical explanation is that the use of a different strategy follows a structural insufficiency at Wernicke's area. Possibly, good readers increase Wernicke's flow and inhibit temporoparietal flow, while poor readers neither increase Wernicke's flow nor inhibit temporoparietal flow. This might suggest that good reading is served by the efficient allocation of a circumscribed left hemisphere region to verbal processing.

Alternatively, the cortical lesions presumed to develop in utero in dyslexic individuals could precipitate an atypical pattern of connectivity, in which axons normally targeted for Wernicke's region find targets within temporoparietal cortex. An example of similarly altered structural development is known from the animal literature on neural development. In studies of neonatal hamsters and ferrets, it was found that simultaneously lesioning visual target areas and auditory or somatosensory afferents resulted in stable, visually driven synaptic contacts at unoccupied auditory or somatosensory sites.[43,44] In dyslexic subjects, the more posterior termination of embryonic axons would constitute a true structural displacement, established prenatally and remaining fixed. So formed, these atypical circuits perhaps would not be as efficient as those established under nonlesion conditions and would explain why fully normal functions would not develop.

If a general displacement model is thus entertained, then the data permit a refinement of the model as follows. The full complement of functions normally represented in Wernicke's area is not entirely displaced to the more posterior locus, since a full displacement should have resulted in a correlation with task accuracy in the posterior area, contrary to the actual findings. Instead, it must be a subset of functions that is displaced (a subset whose activation at the temporoparietal site is quantitatively unrelated to task performance). On the other hand, a simple recruitment of normal temporoparietal functions (as though it were only the strategy that was shifted from Wernicke's area to the temporoparietal region) is apparently inadequate to explain the results. If that were the explanation, then poor childhood readers who improved should have shown a different temporoparietal activation from that shown by those who did not improve.

The fact of compensation must also be acknowledged as the other side of the theoretical coin. Approximately half of the Orton Reading Center group who were impaired as children read normally on the WRAT-R and Gray oral reading tests when evaluated as adults. It is plausible that those individuals who improve do so by tapping compensatory pathways, perhaps by overpractice of traditional strategies[45] or adoption of alternate strategies. We found no correlate of this compensation distinct from childhood reading, however. Thus, compensation can occur in spite of, or even because of, an underlying neural deficit and its associated anomalous activation.

In humans, the cortical correlates of compensation have not yet been described, although it has been shown that near-normal language skills can develop despite early left hemisphere lesions including hemispherectomy.[46] However, a relevant animal model for relatively normal behavior in spite of a lesion is reported by Glass.[47] Visual evoked potentials recorded over the primary visual cortex of monocularly deprived cats are permanently altered, while those recorded from a remote region assume a normal configuration once the sutured eye is opened and the animal is forced to use the "inexperienced" eye to perform certain tasks. Using this model, it would be expected that, given suitable plasticity during a critical period of development, experience would promote neural compensation for a permanent Wernicke's area loss, without necessarily inducing "excess" compensatory function elsewhere.

This study provides the first large-sample evidence that a chronic neural deficit, persisting from childhood, can be measured in vivo in adults in the left hemisphere alone, both as deficient Wernicke's area activation and as excess temporoparietal activation. As such, it not only confirms a left hemisphere anomaly in dyslexia, but also establishes, by example of existence proof, the possibility of individual differences in cortical functional landscapes.

This research was supported by US Public Health Service grant P01HD21887 (to Bowman Gray School of Medicine).

David Stump, PhD, provided quality control of the blood flow data and Cheryl Aine, PhD, helped design the blood flow protocol.

Validation of a Clinical Antisaccadic Eye Movement Test in the Assessment of Dementia

Jon Currie, FRACP; Ben Ramsden; Cheryl McArthur; Paul Maruff

• The ability to generate antisaccades (eye movements deliberately made in the direction opposite to that of a visual stimulus) may be used to assess central nervous system function in a variety of neurologic and psychiatric disorders. However, the usefulness of this paradigm in clinical practice is limited by the need for an oculographic laboratory. We describe a clinical version of such an antisaccadic task and present normative data from 332 subjects. We also examined clinical antisaccades and cognitive performance in 30 patients with Alzheimer's disease, five patients with Huntington's disease, and 12 patients with pseudodementia. In Alzheimer's disease, error rates in the clinical antisaccadic test correlated well with those from a laboratory-based antisaccadic task measured on the same day by infrared oculography, confirming that the clinical antisaccadic test is a valid analog of the more sophisticated laboratory paradigms. Clinical antisaccadic error rates correlated strongly with the severity of dementia in Alzheimer's disease, and correlations with cognitive performance suggested that the clinical antisaccadic test may have some specificity for frontal lobe dysfunction. Patients with pseudodementia had normal clinical antisaccadic error rates, and the test may therefore be of use in differentiating dementia from pseudodementia. This clinical antisaccadic test provides a simple, reliable, and inexpensive quantitative clinical tool that is of value in the assessment of disturbances of higher cortical function.

(*Arch Neurol.* 1991;48:644-648)

Laboratory measurement of eye movements has assumed increasing importance in the assessment of abnormalities of central nervous system function in a variety of neurologic and psychiatric disorders that include Alzheimer's disease,[1-4] Huntington's disease,[5,6] progressive supranuclear palsy,[7] Parkinson's disease,[8] schizophrenia,[9,10] and the acquired immunodeficiency syndrome.[11,12] Of particular value is the analysis of voluntary eye movements that result from more complex visual cognitive or memory tasks, such as the ability to generate antisaccades.[3,5,7,9,10,12] *Antisaccades* are eye movements deliberately made in the direction opposite to that of a suddenly presented peripheral stimulus and require the suppression of any reflexive eye movement toward that stimulus.[13-15] The ability to suppress a reflexive glance at a target, but to use the target's visual information accurately to move the eyes in the opposite direction, is thought to utilize corticotectal pathways that originate from several areas of the frontal cortex and descend via the caudate nucleus, substantia nigra, and superior colliculus.[7,10,15-18] Abnormalities of both antisaccadic accuracy and latency occur with cortical and subcortical lesions that involve these areas.[5-7,15]

Two major drawbacks to the routine use of high-resolution eye movement measurement in clinical neurologic practice are the need for a laboratory setting and the cost of the equipment required. Although laboratory recording techniques significantly increase the ability to detect and quantify different eye movement abnormalities,[19] clinical examination of eye movements can still play a valuable role in the examination of many neurologic diseases.[20] This report describes and validates a clinical antisaccadic eye movement test and illustrates its use in the clinical assessment of dementia in patients with Alzheimer's disease.

SUBJECTS AND METHODS

Clinical Protocol for the Antisaccadic Eye Movement Test

The subject was seated facing the examiner, who positioned his hands equidistantly from the midline in the subject's left and right visual fields, with each index finger extended in the manner commonly used to test visual fields by confrontation. The stimulus for each trial was two to five rapid, repeated flexions of one or the other of the examiner's index fingers. A saccadic and antisaccadic task were performed, the saccadic task acting as a training session for the antisaccadic test.

Saccadic Task.—The subject was instructed to remain looking at the examiner's nose until one of the examiner's index fingers moved and then as quickly as possible to "turn your eyes only and look at the finger that moves." Following either a correct or incorrect response, the subject was then instructed to look back at the examiner's nose, and each subsequent trial was not begun until this central fixation was clearly reestablished. The task was therefore paced by the subject's responses. A random sequence of six to 10 saccades to the subject's right and left, looking at the moving finger, was then performed. This allowed the subjects to learn not to anticipate a predictable sequence of steps from one side to the other, and to learn to move only their eyes to look at the target and not to point with the hand or verbally indicate left or right, as is commonly done with visual field testing. The subject's response was recorded as the direction of the initial movement of the eyes from the midline in response to the movement of the examiner's finger. A correct response for the saccadic task was an initial eye movement toward the moving finger. The saccades were continued until the subject could perform the task correctly.

Antisaccadic Task.—The subject was then informed that the task had changed and given the following instruction by the examiner: "When my finger moves, do not look at the finger that moves, look immediately in the opposite direction at the finger that does not move." For the antisaccadic task, the correct response was an initial eye movement to the side opposite that of the moving finger, and any initial eye movement across the midline toward the moving finger was recorded as an error, even if a subsequent correction toward the nonmoving finger was made. If comprehension of the task seemed incomplete, the subject was asked to point with a finger at the correct, opposite, nonmoving target, to demonstrate that the principles of the test were understood. Once the concept of the task had been established, 25

trials were performed with random determination of laterality, and again central fixation was reestablished after each trial before continuing to the next trial. The first five of these 25 trials were regarded as practice trials and were not scored, and the instructions could be repeated during these five trials to ensure that the task was understood. The examiner then scored the number of correct responses for the subsequent 20 trials. Brief positive verbal reinforcement was given after each trial, and the instructions for the task were repeated if two successive incorrect responses occurred. A percentage error rate was calculated for the antisaccadic task as follows: (Number of antisaccadic errors/total number of trials) × 100.

In 15 control subjects (eight male, seven female; mean age, 43 years; age range, 15 to 80 years), the eye movement responses elicited during this clinical antisaccadic testing were recorded using infrared scleral reflectance oculography (IRIS, Skalar, Delft, the Netherlands) and a computer timing switch initiated by the flexion movement of the examiner's finger (Fig 1). In these 15 control subjects and in 15 subjects with Alzheimer's disease, the error rate in the clinical antisaccadic testing was also correlated with the error rate recorded on the same day by infrared oculography during a typical laboratory-based antisaccadic task, similar to that described by Lasker et al.[5] In this laboratory-based task, subjects fixated a central green light-emitting diode target, which was then extinguished simultaneously with the appearance of a peripheral red target positioned either to the left or right of midline. The red target was laser generated and computer controlled using X-Y mirror galvanometers (General Scanning, Watertown, Mass). Displacement and timing of the appearance of the peripheral red target was pseudorandom, with 7.5°, 10°, or 15° steps and 2.0- or 2.5-second intervals after fixation. The subject was instructed not to look at the red target but immediately to look at an imagined point an equal distance on the opposite side of the midline and to hold the gaze there until returning to central fixation with the reappearance of the central green target.

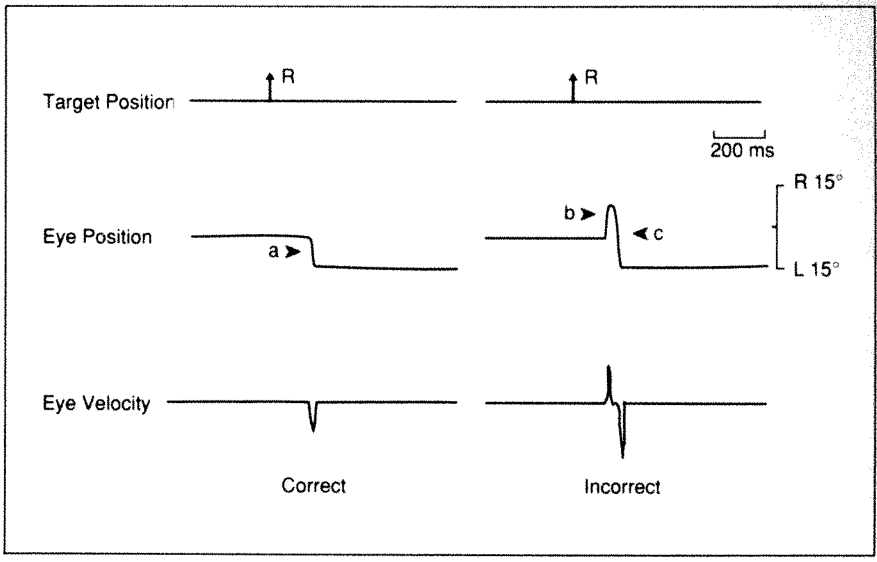

Fig 1.—Infrared eye movement recordings during the clinical antisaccadic task for a "moving finger" target to the right (R) of the subject's midline showing a correct leftward eye movement in the direction opposite to that of the moving finger (a) and an incorrect rightward initial eye movement toward the moving finger (b) with a subsequent corrective eye movement to the opposite side (c). Note also that the latency of response for the correct antisaccade is longer than for the reflexive, incorrect antisaccade.

Subjects

Control Subjects.—There were 332 control subjects, including 180 healthy volunteers (83 male, 97 female; age range, 15 to 89 years, with a mean age [±SD] of 41±18 years) and 152 hospital inpatients and outpatients with a variety of nonneurologic illnesses (65 male, 87 female; age range, 15 to 87 years, with a mean age of 52±21 years).

Patient Groups.—There were three patient groups. First was a group of 30 patients with clinically diagnosed Alzheimer's disease (16 male, 14 female; age range, 49 to 89 years, with a mean age of 67±8 years). Their disease was diagnosed according to National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer's Disease and Related Disorders Association criteria,[21] including gradual deterioration of memory and intellectual function over a period of at least 2 years, an ischemic score[22] below 4, and computed tomographic or magnetic resonance imaging scanning to exclude coexisting focal structural disease. All patients had severity of dementia assessed by the Mini-Mental State examination (MMSE).[23] Where possible (n=20), a neuropsychometric test battery was administered, which included the modified Weigl Color Form Sorting (CFS) test,[24] the Digit Span Forward subtest of the Wechsler Adult Intelligence Scale,[25] the Memory Quotient of the Wechsler Memory Scale,[26] and the Buschke Selective Reminder Test.[27]

Second was a group of 10 patients with depressive pseudodementia (*Diagnostic and Statistical Manual of Mental Disorders, Revised Third Edition* [*DSM-III-R*] criteria[28(pp106,221)]) (six male, four female; age range, 35 to 84 years) and two with factitious disorder with psychological symptoms (*DSM-III-R* criteria[28(pp318-319)]) (both female).

Third was a group of five patients with Huntington's disease (four male, one female; age range, 18 to 64 years).

The research protocol was approved by the Ethics Committee of the Mental Health Research Institute of Victoria, Parkville, Australia. Subjects or their next of kin gave informed consent after the nature of the testing had been fully explained.

Statistical Analysis

In general, comparisons between groups were performed by analysis of variance with post hoc comparisons by Scheffé's test. Correlations were performed by the Pearson Product-Moment Correlation Coefficient or Spearman Rank-Order Correlation, as indicated. Significance was taken at $P \leq .01$ unless otherwise stated.

RESULTS

Control Subjects

In the 15 control subjects where the clinical antisaccadic task was recorded with infrared oculography, the mean latency for a correct antisaccade was 324±96 milliseconds, and for an incorrect, reflexive saccade toward the target the mean latency was 282±159 milliseconds (Fig 1). By comparison, for the laboratory-based task with the same subjects, the latency for a correct antisaccade was 336±93 milliseconds and for an incorrect reflexive saccade it was 285±109 milliseconds. Infrared oculography also demonstrated that an examiner could accurately identify all correct and incorrect saccades performed during the clinical task.

For the clinical antisaccadic task, the percent error rate was independent of subject age above 15 years ($r = .122$, $P < .02$), and there was no statistical difference between the error rates of male and female subjects in either the healthy volunteer group or the hospital inpatient and outpatient group. The results for male and female subjects were therefore combined across all ages within each of these two control subject groups (Fig 2). The mean percent error rate in the hospital control group (10.3%±6.3%) was slightly higher than in the healthy volunteer group (8.3%±6.7%), but this difference did not reach significance ($P = .08$). Results from both groups were combined together (mean, 9.2%±6.6%), and a 99th percentile error score control range was defined for the antisaccadic task (Fig 3). Scores of 30% or greater were considered abnormal. By comparison, for the laboratory-based task, the mean percent error rate was 6.2%±7.8%. From the total control population, a subgroup (n = 152; age range, 49 to 87 years with a mean age of 65 ± 10 years) was also selected that was age matched with the group with Alzheimer's disease. For this control subgroup, the mean percent error rate was 10.1% ± 6.3%, and scores of 30% or greater were also abnormal at the 99th percentile.

Clinical Patient Groups

Twenty-five (83%) of the 30 patients with Alzheimer's disease had impaired performance (≥30% error rate) in the clinical antisaccadic task, and the percent error rate correlated strongly with the severity of dementia present, as measured by the MMSE score ($r = -.935$, $P < .0001$; Fig 4, left). All 26 patients with MMSE scores less than 25 (abnormal performance defined by age-specific norms[29]) had antisaccadic error rates of 30% or greater. There was also a strong correlation between the clinical antisaccadic error rate and the error rate in performing the laboratory antisaccadic task as measured by infrared oculography ($r = .921$, $P < .0001$; Fig 5). In almost all cases, the percent error rates from the laboratory-based task were higher than those with the clinical antisaccadic test. The clinical antisaccadic percent error rate correlated strongly with patients' scores on the CFS test ($r = -.917$, $P < .0001$; Fig 4, right) and had intermediate correlations with tests of memory function (Memory Quotient, $r = -.807$, $P < .001$; Selective Reminder Test, $r = -.716$, $P = .004$) but poor correlation with scores on the Wechsler Adult Intelligence Scale Digit Span Forward subtest ($r = -.489$, $P > .05$).

In contrast to patients with Alzheimer's disease, the antisaccadic error rates in patients with depressive pseudodementia or factitious disorder were normal once compliance for testing was gained, despite significantly impaired global levels of cognitive performance (Fig 6).

All five patients with Huntington's disease had increased antisaccadic error rates that were slightly higher than

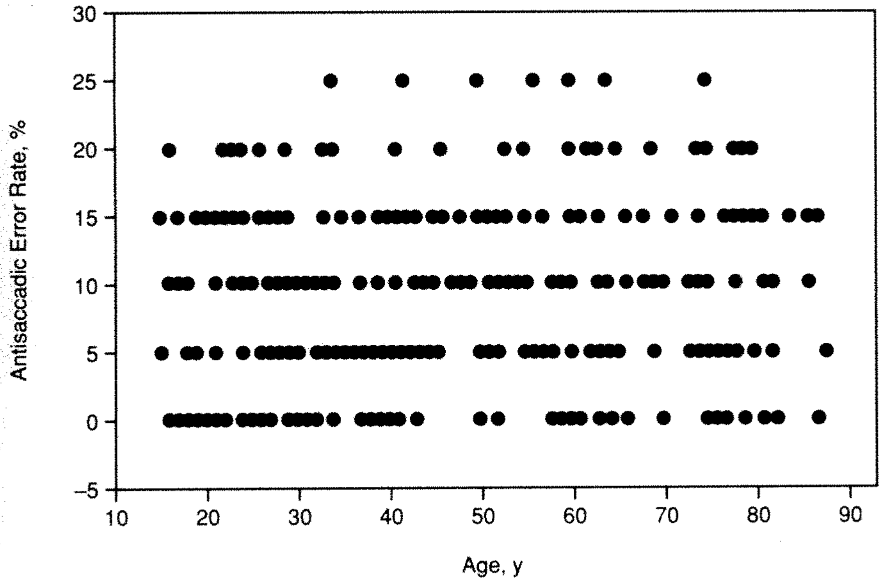

Fig 2.—Clinical antisaccadic percent error rate for all control subjects over the age of 15 years (n = 332), showing no correlation of percent error rate with subject age.

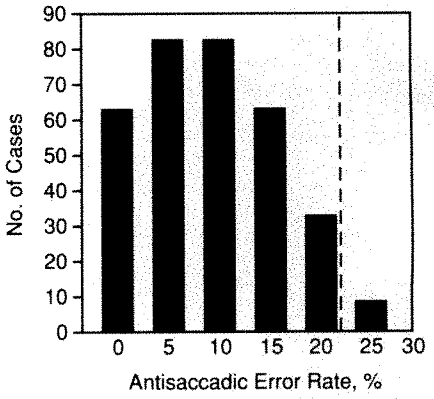

Fig 3.—Frequency histogram showing the distribution of percent error rates for the clinical antisaccadic test in the control population. The error rate control range was 0% to 25%, and an error rate above 25% was considered to be abnormal. The vertical broken line indicates mean + 2 SDs.

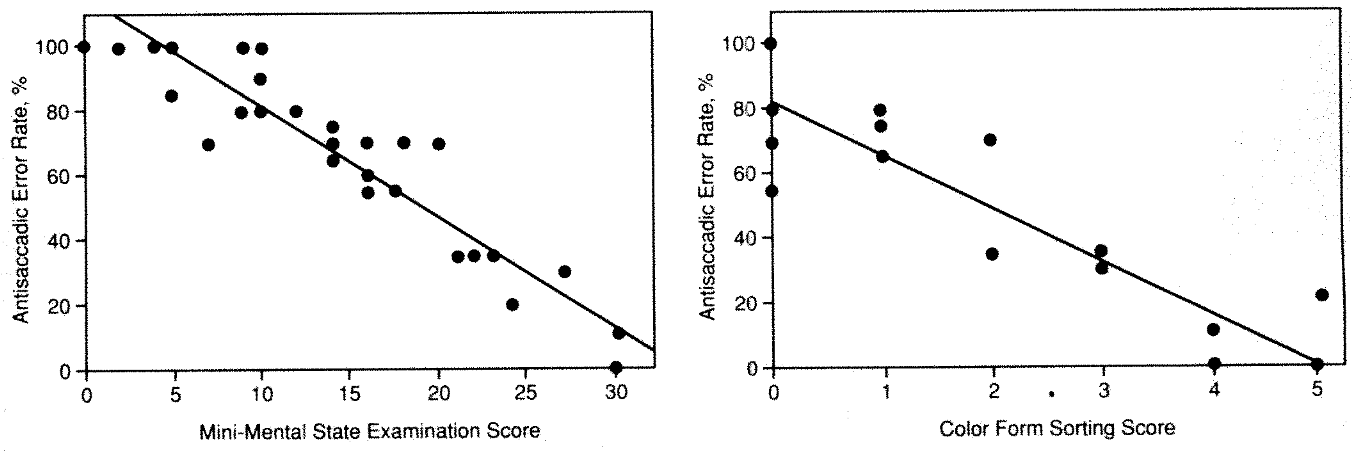
Fig 4.—Correlation in 30 patients with Alzheimer's disease between the clinical antisaccadic percent error rates and Mini-Mental State examination scores (left) ($r = -.935$, $P < .0001$) and Color Form Sorting scores (right) ($r = -.917$, $P < .0001$).



those for patients with Alzheimer's disease with similar MMSE scores (Fig 6).

COMMENT

The clinical antisaccadic test is simple to administer and provides a measure of oculomotor function in patients with Alzheimer's disease that correlates well with the severity of dementia.

Correct performance of an antisaccadic task requires a subject to suppress the reflexive, prepotent tendency to look at a newly presented visual stimulus, but to use the target's visual information to move the eyes immediately in the opposite direction.[5-7,13-17] This requires the generation of both excitatory and inhibitory oculomotor signals, as well as utilizing representational memory of what the target means, rather than using the direct stimulation that is immediately present in the target.[17] In monkeys, the control of such voluntary, purposive saccades is probably dependent on the interaction of a variety of regions in the frontal cortex,[17] including the areas of the frontal eye fields (FEFs)[18,30] and principal sulcus[31] in the dorsolateral prefrontal cortex, and the supplementary eye field region in the dorsomedial frontal cortex.[32] The prefrontal cortex may issue both facilitatory and inhibitory motor commands that could accomplish the dual task of commanding the correct response while disallowing or inhibiting the incorrect one.[17,18] For example, the FEF provides both direct targeting signals to the superior colliculus, as well as foveally responsive signals, which may trigger or suppress collicular saccades.[18] In addition, the FEF may influence the substantia nigra, via an FEF–caudate nucleus pathway.[16,18,33] The FEF projects to the head of the caudate, which contains a presaccadic signal similar in quantity but reversed in sign from that of the substantia nigra. This frontal-caudate signal may inhibit the substantia nigra and result in release of the tonic nigral suppression of the superior colliculus.[18,33] Similarly, the supplementary eye field of the dorsomedial frontal cortex provides longer-latency saccadic signals to the superior colliculus related to goal-directed and self-initiated saccades.[32] These pathways from the frontal cortex and basal ganglia to the superior colliculus control the generation of volitional, visually guided eye movements[7,15,18,30] and may help to suppress reflexive glances toward visual stimuli by inhibiting the superior colliculus.[7,15,18]

Impaired antisaccadic performance is usually attributed to lesions that involve these pathways.[5,7,15,17] A prominent feature in subjects with frontal lobe lesions is distractibility due to excessive dependence on, or sensitivity to, external cues.[17,34,35] In the antisaccadic task, this is demonstrated by an inability to suppress forbidden, reflexive eye movements toward each newly presented target. In addition, subjects with frontal lobe lesions have difficulty using the representational information from the initial target to move the eye correctly in the opposite direction,[17] and often the correct eye movement is only triggered if a second cue is subsequently provided to indicate the correct, expected eye position.[15]

As in the laboratory-based antisaccadic paradigm, the clinical antisaccadic task described herein also provides an initial target (moving finger) with which to assess the ability to suppress incorrect reflexive saccades (distractibility). The clinical task does differ slightly from the laboratory task in that the secondary cue for the correct location for the antisaccadic eye movement (the opposite, nonmoving finger) is continually present. However, for our 15 control subjects, performance in both the clinical and laboratory tests was similar. Our results using the clinical antisaccadic test are also in close agreement with previously reported results from laboratory antisaccadic paradigms.[3,5,7,9,10,15] For control subjects, the clinical test error rates (0% to 25%) and latencies for both correct (324 milliseconds) and incorrect (282 milliseconds) antisaccadic responses accord well with those reported previously for laboratory control subjects (error rates, 5% to 20%[9,15]; correct antisaccadic latencies, 250 to 364 milliseconds[5,9]; latencies for incorrect saccades, 219 to 311 milliseconds[5,10]). As with laboratory paradigms, the latency for correct clinical antisaccades was longer than for incorrect (reflexive) initial eye movements[15] (Fig 1).

Patients with Alzheimer's disease performing the clinical antisaccadic test showed difficulty both in suppressing incorrect responses and in generating correct responses in the opposite direction. In these patients, the strong correlation of clinical error rates with laboratory error rates (Fig 5) also supports the validity of the clinical paradigm. How-

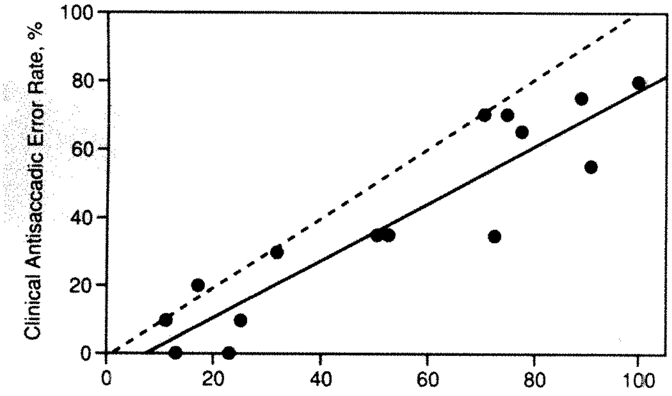


Fig 5.—Correlation in 15 patients with Alzheimer's disease between the percent error rates in the clinical antisaccadic task and percent error rates in a laboratory-based antisaccadic task performed on the same day. The dotted line represents the ideal regression if the error rates in the two tasks were equal, and the solid line is the linear regression for the actual error values obtained. The laboratory-based task has higher percent error rates than the clinical test in almost all cases (values lying below the dotted line) and is therefore likely to be a more sensitive test (r=.921, P<.0001).

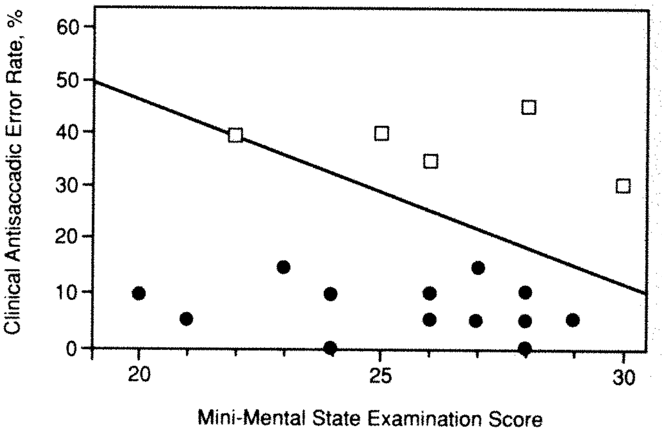

Fig 6.—Correlation of clinical antisaccadic percent error rates and Mini-Mental State examination scores in 12 patients with depressive pseudodementia (solid circles) and five patients with Huntington's disease (open squares), illustrated in relation to the linear regression line for percent error rates in patients with Alzheimer's disease from Fig 4, left. In general, error rates in patients with Huntington's disease are higher and in patients with pseudodementia are lower than in patients with Alzheimer's disease.

ever, the higher laboratory error rates in patients with Alzheimer's disease suggest that laboratory techniques are still more sensitive than clinical examination.[19] In Alzheimer's disease, the error rates for the clinical antisaccadic test correlated strongly with the severity of dementia present (Fig 4, left). Fletcher and Sharpe[3] have previously reported decreased ability to make antisaccades in patients with Alzheimer's disease but did not comment on any correlation of error rate with disease severity. Our findings suggest that the clinical antisaccadic test may be useful in the clinical assessment of dementia in Alzheimer's disease and in monitoring disease progression. The striking difference in error rates between patients with Alzheimer's disease and those with depressive pseudodementia functioning at comparable levels, as measured by MMSE scores (Fig 6), suggests that the test may also be useful in distinguishing between these two conditions.

Guitton et al[15] have demonstrated that frontal lobe lesions give rise to difficulties in generating antisaccades. In Alzheimer's disease, Fletcher and Sharpe[3] have also attributed antisaccadic abnormalities to neuronal degeneration in the frontal cortex. The CFS is a test that particularly relies on frontal lobe function.[36(pp484-486)] In our patients with Alzheimer's disease, there was a strong correlation of antisaccadic error rates with performance in the CFS test (Fig 4, right), but not with Digit Span Forward. Digit Span Forward is primarily a measure of the efficiency of attention and is relatively resistant to the effects of dementia but may be influenced by factors such as anxiety.[36(pp266-270)] These findings support the conclusion that frontal lobe damage may be contributing to impaired antisaccadic performance in patients with Alzheimer's disease.

Saccadic distractibility and poor antisaccadic performance have also been reported in patients with Huntington's disease[5] and progressive supranuclear palsy,[7] which may reflect abnormalities of basal ganglia function rather than frontal lobe function. In our patients with Huntington's disease, the antisaccadic error rates were higher than those in patients with Alzheimer's disease with comparable MMSE scores (Fig 6). Lasker et al[5] reported a similarly high antisaccadic error rate (mean, 60%) in patients with mild Huntington's disease, and no patients made fewer than 20% errors. These findings may reflect the important role that the basal ganglia and other subcortical structures play in the initiation of voluntary saccades and maintenance of fixation.

The antisaccadic test that we have described appears to be a valid clinical analog of the more sophisticated laboratory-based antisaccadic paradigms. Error rates in this clinical test correlate well with the severity of dementia in Alzheimer's disease and may have some specificity for frontal lobe dysfunction. Although the abnormalities that are detected with this clinical antisaccadic test are not necessarily specific for any single disease, we believe that the test provides a simple, robust, and inexpensive quantitative clinical tool that will be of value in the assessment of disturbances of higher cortical function.

We wish to thank Liza Bermingham for her expert editorial assistance and help in manuscript preparation.

Literary Neurologic Syndromes

Alice in Wonderland

Loren A. Rolak, MD

• **Many neurologic syndromes are named for literary characters. For example, the "Alice in Wonderland" syndrome of altered body perceptions, usually caused by migrainous ischemia, is so called because of the resemblance of its symptoms to the fluctuations in size and shape that plague the main character in Lewis Carroll's 1865 novel *Alice in Wonderland*. The medical symptoms of distorted body images match the literary description so precisely that illustrations from the original book depict them very accurately. Because Lewis Carroll suffered from classic migraine headaches, scholars have speculated that he may have experienced this syndrome himself.**

(*Arch Neurol*. 1991;48:649-651)

The "Alice in Wonderland" syndrome refers to distortions of body image, usually in the setting of classic migraine headaches. Todd[1] gave the syndrome its literary name in his report in the November 1, 1955, issue of the *Canadian Medical Association Journal*, describing "a singular group of symptoms intimately associated with migraine and epilepsy." However, the first description of the condition was by Lippman[2] in the *Journal of Nervous and Mental Diseases* in 1952.

In his report, titled "Certain Hallucinations Peculiar to Migraine," Lippman[2] described seven patients with migraine headaches who described altered perceptions of their body image. Often, these appeared as migraine equivalents, in which the hallucinations constituted the entire attack; there was no accompanying headache, scotoma, nausea, or any other physical symptom to lend credence to these bizarre distortions. Lippman used direct quotations from his patients to emphasize the peculiar alterations of bodily perception that constitute this syndrome. His patient 2 had the sensation of her left ear "ballooning out 6 inches or more." His patient 3 described the following:

> I felt that I was very tall. When walking down the street, I would think I would be able to look down on the tops of others' heads, and it was very frightening and annoying not to see as I was feeling. The sensation was so real that when I would see myself in a window or full-length mirror, it was quite a shock to realize that I was still my normal height of under 5 feet.

Lippman's patient 7 described his sensations as follows: "The body is as if someone had drawn a vertical line separating two halves. The right half seems to be twice the size of the left half." Victims were aware of the illusory nature of their perceptions but were sometimes reluctant to admit to them for fear of being thought insane.

Some of these patients also had distortions of time sense, such as "I felt as if I was going fast," and "I felt as if everyone was talking too fast and moving too fast." The patients' ages ranged from 11 to 72 years, although the syndrome, like migraine, appears to be more common in young people, even children. Although a variety of causes, including viral encephalitis[3] and epilepsy,[2] subsequently have been reported for the Alice in Wonderland syndrome, it is almost pathognomonic of migraine.[4]

This sensation of formed body distortions, a type of metamorphopsia, probably results from migrainous ischemia. Different authors analyzing this syndrome have come to different conclusions about its localization, some asserting that the pathology affects the anterior occipital lobe, while others implicate the posterior temporal lobe. Most, however, believe that the symptoms arise in the posterior parietal lobe, especially from the nondominant hemisphere.[2-4]

The name of the syndrome comes from the book most people know as *Alice in Wonderland*,[5] although its actual title is *Alice's Adventures in Wonderland*, often printed with its companion piece *Through the Looking-Glass and What Alice Found There*. The story was published in 1865 by Charles Lutwidge Dodgson, under the pseudonym Lewis Carroll. Dodgson was an English gentleman who attended Rugby and Oxford University, where he became a professor of mathematics, specializing in Euclidean geometry. He was considered a first-class mathematician, and, indeed, his fictional works, such as *Alice in Wonderland*, have been analyzed from the standpoint of mathematical theory.[6] In fact, the action in the book corresponds to a real and complex chess game, with the adventures and movements of Alice, the Red Queen, the White Knight, and other characters representing actual moves on a chessboard (Fig 1).

An episode of changing height is one of the most famous scenes in the book. At one point, Alice finds a bottle marked

Fig 1.—The chess problem that is the basis for the actions and movements of the characters in *Alice in Wonderland,* as the white pawn (Alice) advances to capture the red queen (R. Q.) and win the game. Q indicates queen; W. Q., white queen; W. Kt., white knight; R. Kt., red knight; K. R., king's rook; K. B., king's bishop; Q. B., queen's bishop; and K. sq., king's square.

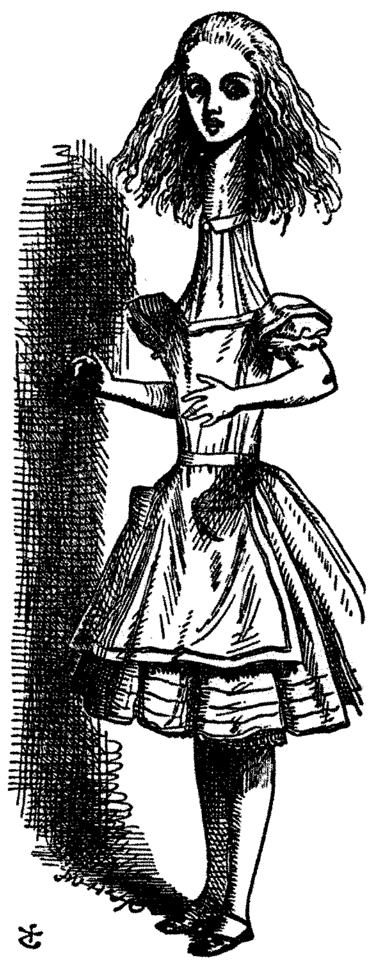

Fig 3.—Lippman's patient 6 indicated that "I get all tired out from pulling my head down from the ceiling. My head feels like a balloon; my neck stretches and my head goes to the ceiling. I've been pulling it down all night long." This description matches this original illustration from *Alice in Wonderland.*

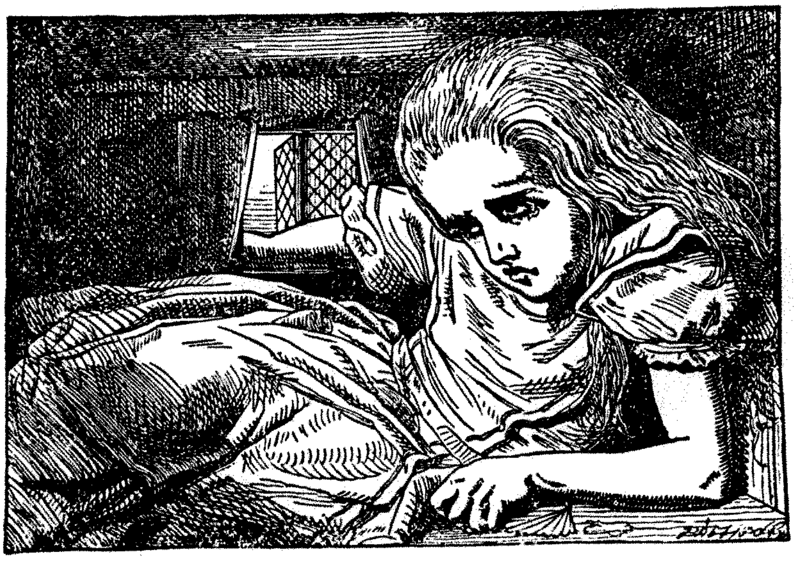

Fig 2.—Lippman's patient 2 indicated she "feels that her body is growing larger and larger until it seems to occupy the whole room." This description matches this original illustration from *Alice in Wonderland.*

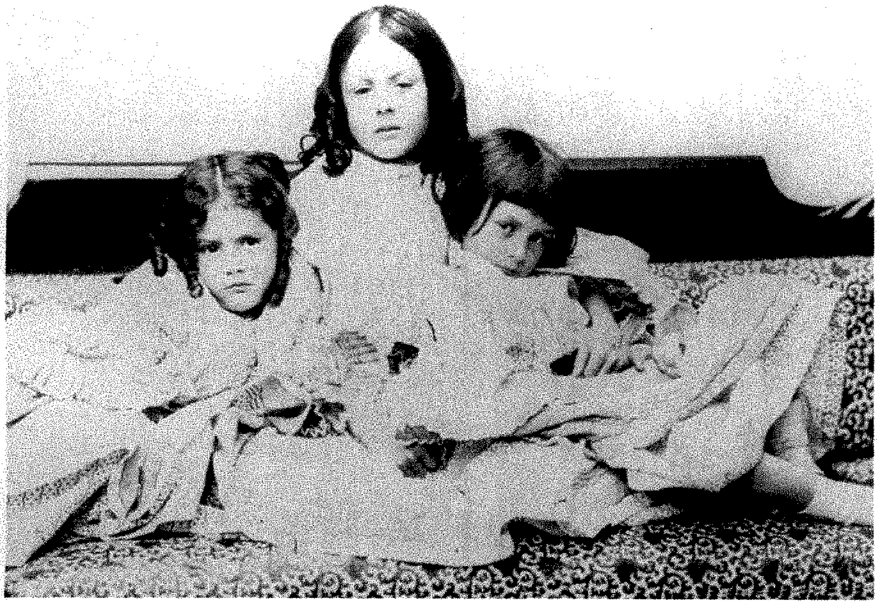

Fig 4.—A photograph by Charles Dodgson (pseudonym, Lewis Carroll) of the Liddell sisters. From left to right, Alice (the heroine of the books), Lorina, and Edith.

"Drink Me," which she does, causing her to shrink. Soon after, she eats a piece of cake marked "Eat me" and begins to grow. Alice's size continues to fluctuate through a series of adventures with the Mad Hatter, the Cheshire Cat, the Walrus, the Carpenter, and other characters. Figures 2 and 3 are reproductions of the original drawings by Sir John Tenniel for the first edition of *Alice in Wonderland* in 1865, illustrating some of these body distortions. The figure legends are exact quotes from the patients in Lippman's original article, juxtaposed with the illustrations to show how perfectly the medical syndrome he described fits the literary source.

Dodgson knew many men from upper-class Victorian society, including many physicians. His interests in medical matters and in children joined in his will, in which he left a provision, still maintained today, for perpetual endowment of a bed in The Children's Hospital, London, England. His enjoyment of children prompted him to write books for them, and "Alice" in Wonderland was a real person—Alice Liddell, the daughter of his dean at Oxford University (Fig 4).

We know that Dodgson suffered from classic migraine headaches, which he described as "bilious headaches," preceded by eye disturbances and fortification scotomas. Although his diaries do not mention headaches until many years after the *Alice in Wonderland* books were published and never relate any body image hallucinations,[7] some authors speculate that Dodgson may have experienced body distortions as a feature of his own migraines and that "Alice trod the paths of a wonderland well known to her creator."[2]

Central Nervous System Germinomas

A Review

Michael Bruce Horowitz, MD, Walter A. Hall, MD

• The germinoma represents a less malignant form of germ cell tumor. Depending on the individual's age, this neoplasm constitutes approximately 0.1% to 3.4% of all intracranial tumors. The embryologic origin remains a mystery; however, current theories implicate an aberration in primordial germ cell migration. Clinical presentation depends on tumor location and may involve endocrine, hypothalamic, visual, and cognitive dysfunction. In evaluating midline intracerebral masses, it is imperative that one be aware of the various radiologic appearances, endocrinologic changes, and chemical markers that help to distinguish germinomas from other neoplasms that appear in the pineal, suprasellar, and periventricular regions. Only through the careful evaluation of all available studies can the physician institute appropriate therapies such as biopsy, radiation, and chemotherapy. This article focuses on the epidemiology, embryology, clinical presentation, means of diagnosis, treatment, and outcome of this rare neoplasm.

(*Arch Neurol.* 1991;48:652-657)

The germ cell tumor, a rare finding in the neuraxis, represents a neoplasm that, if properly diagnosed and managed, can be eradicated or controlled in the adult and pediatric populations.[1,2] Under this broad category, in order of frequency of appearance in the central nervous system in all age groups, lie the subcategories of germinoma (40%); mixed tumor (30%); teratoma (20%); and yolk sac tumor, embryonal carcinoma, and choriocarcinoma (10%).[2] These neoplasms most often involve the reproductive organs but may also appear in extragonadal sites such as the sacrococcygeal region, intracranial region, abdomen, retroperitoneum, thoracic cavity, pharynx, neck, thyroid, spinal cord, meninges, bladder, prostate, and soft tissues of the occipital region. Germ cell tumors arising within the ovary rarely occur before the fifth year of life. In contrast, testicular germ cell tumors are frequently found before the fifth year of life and present as a painless mass with an associated hydrocele. Pure germinomas are rare in children younger than 5 years.[1]

Pure germ line tumors are called germinomas. Differentiated germ cell tumors may be divided into embryonic (embryonal carcinoma and mature or immature teratoma) and extraembryonic (choriocarcinoma and yolk sac or endodermal sinus tumors) growths. When organized according to increasing malignant potential, these tumors are germinoma, teratoma, embryonal carcinoma, embryonal sinus tumor, and choriocarcinoma.[3] Each tumor represents the malignant correlate of a normal stage of embryonic development.[3] Germinomas arise from the primordial germ cell; teratomas arise from the differentiated embryonic cell layers; embryonal carcinoma develops from a pluripotential cell of the embryo proper; endodermal sinus tumors represent tissue from extraembryonic yolk sac endoderm; and choriocarcinoma arises from extraembryonic trophoblastic tissue.[3] This article focuses on the epidemiology, embryology, clinical presentation, means of diagnosis, treatment, and outcome of a rare treatable neoplasm, the germinoma.

EPIDEMIOLOGY

The incidence of germinomas varies among Asia, Europe, and the Western Hemisphere. Depending on an individual's age, germinomas constitute 0.1% to 3.4% of all intracranial tumors.[1,3-5] The Armed Forces Institute of Pathology reported that germ cell tumors represented 1.8% of primary intracranial tumors in individuals younger than 20 years, and germinomas represented 16.7% of these tumors.[6] Other reports indicate that germ cell tumors represent 6.5% of intracranial tumors seen during the first two decades of life.[6] Studies evaluating individuals of all ages, however, have shown germinomas to represent up to 65% of intracranial germ cell tumors.[3] The incidence of germ cell tumors in Japan far exceeds that found in other nations. A review of 20 192 brain tumors in Japan between 1969 and 1978 revealed 435 germinomas (2.7%) in all age groups, 184 of which were in children (7.8% of primary pediatric brain tumors).[7] Other series report that 0.3% to 9.4% of intracranial neoplasms in Japan are germinomas.[3-5] Just as it appears that there is a predilection for race, there also seems to be a tendency for these tumors to develop in males. Germ cell tumors have a male-female ratio of 2.24:1, while germinomas have a male-female distribution of 1.88:1.[3]

EMBRYOLOGY

Germ cell tumors arise because of neoplastic changes during embryonic development. Intracranial germ cell tu-

mors occur in the pineal region, suprasellar-retrochiasmal area, pituitary fossa, posterior third ventricle, interpeduncular and quadrigeminal plate region, cerebellar vermis, thalamus, and walls of the lateral and third ventricles.[8] How these neoplasms come to develop in the various intracranial sites is not known.

Mature male and female germ cells are derived from primordial germ cells that appear in the yolk sac wall at the end of the third week of development.[9] The development and migration of these cells has been studied in a variety of organisms. In ascarides and in insects, at the point of the first egg division, long V-shaped chromosomes are found in blastomeres giving rise to germ cells. Blastomeres destined to become somatic cells contain fragmented versions of these chromosomes. In birds and reptiles, primordial germ cells are located in the extraembryonic blastoderm. These cells migrate into spaces between endoderm and mesoderm, penetrate blood vessels of the area vasculosa, and eventually reach the germinal ridges. Cells that stray during migration later degenerate.[10,11] In man, the origin of primordial germ cells in the embryo has not been studied. These cells are located in the endodermal epithelium of the yolk sac near the allantoic stalk. From here, cells migrate into the adjoining mesenchyme and eventually settle in the germinal ridges.[10]

Primitive germ cells arise from endoderm, migrate into adjacent mesoderm, stimulate blood vessel formation, and disseminate throughout the embryo.[8] Work performed in birds and reptiles has led to the idea that intracranial germinomas develop secondary to circulatory dispersion of cells in the embryo. An alternative theory, proposing that intracranial germinomas arise from misplaced multipotential fragments of the embryonic primitive streak, was supported by the close proximity of the most rostral portion of the primitive streak to the pineal anlage.[2,8-11] Hypothalamic and retrochiasmal tumors are not explained by this theory. Jennings et al[3] stated that the appearance of the ventral hypothalamus at 35 to 38 days coincided with the major migration phase of human germ cells. The presence of germ cell tumors in diencephalic loci suggested that local ontogenic, synaptic, and functional interrelationships may exist between the developing diencephalic structures, the pineal gland, the suprasellar region, and germ cells.[3]

CLINICAL PRESENTATION

Signs and symptoms associated with germinomas most commonly include diabetes insipidus (41%), visual field defects (33%), and hypothalamic/pituitary dysfunction (33%). Pituitary/hypothalamic abnormalities include delay or regression of sexual development (16%); hypopituitarism (16%); growth failure (9%); precocious puberty (5%); fluctuations in blood pressure, heart rate, respiration, and temperature; gastric motility; and alterations in memory, mood, appetite, and emotional behavior. Additional clinical features associated with germinomas are hydrocephalus (21%), obtundation (15%), Parinaud's syndrome (14%), pyramidal tract signs (14%), ataxia (9%), diplopia (10%), seizures (3%), choreoathetosis (2%), dementia (2%), and psychosis (1%).[2,3] Pineal region tumors generally present first with Parinaud's syndrome and hydrocephalus, while suprasellar tumors present with endocrinopathy, visual loss, and diabetes insipidus.[12]

Germinomas disseminate from the suprasellar and pineal regions by direct infiltration or spread along cerebrospinal fluid pathways.[3] Distant sites of spread include the cavernous sinus,[13] hypothalamus,[3,12] thalamus,[12,14,15] basal ganglia,[12,14-15] septum pellucidum,[12] ventricular system near the foramen of Monro and the trigone of the lateral ventricle,[15] parietal region,[17] cerebellar vermis,[15] frontal lobe,[15] and paraventricular region.[15] Cavernous sinus involvement[13] presents with headache, decreased visual acuity, third nerve palsy, orbital pain, complete ophthalmoplegia, and facial numbness. Coffey[12] described a 24-year-old woman with a hypothalamic germinoma who had anterograde and retrograde amnesia, hyperphagia, visual obscurations, headache, and normal endocrine function. Damage to the fornix, mamillothalamic tracts, and ventromedial thalamus was presumably responsible for the patient's symptoms.

Ono et al[14] described eight patients with germinomas of the thalamus and basal ganglia (third most common site of occurrence). These patients presented with hemiparesis (100%), mental disturbance (63%), increased intracranial pressure (38%), and progressive dystonia with involuntary movements (25%). Tumor affecting the cerebellum can cause dizziness, tinnitus, and gait abnormality.[15]

The endocrinologic presentation and evaluation of germinomas is an interesting and important topic. With proper diagnostic testing and institution of appropriate treatment, the patient can be returned to normal hormonal balance. Multiple endocrine abnormalities may develop as a consequence of tumor infiltration. Because of this infiltration, germinomas have a greater incidence of endocrinopathy than do craniopharyngiomas.[18] Diabetes insipidus with polyuria and polydipsia occurs in 93% of suprasellar germinomas and in 41% of germinomas, regardless of location.[3,16] Growth hormone release is impaired earlier than gonadotropin release. Low levels of luteinizing hormone and follicle-stimulating hormone and poor response to luteinizing hormone–releasing hormone have been seen. Thyroid-stimulating hormone and adrenocortical hormone are less frequently affected. Some studies have shown delayed and/or exaggerated plasma thyroid-stimulating hormone response to thyroid-releasing hormone. In these patients, despite an elevated level of thyroid-stimulating hormone, a hypothyroid state often exists because the thyroid-stimulating hormone is biologically less active.[18] For unknown reasons, adrenocortical hormone response to exogenous corticotropin-releasing factor is often delayed in persons with hypothalamic germinomas.[18] Growth hormone release in response to exogenous gonadotropin-releasing factor is another indicator of hypothalamic invasion.[18] With hypothalamic destruction or interruption of the hypothalamic-pituitary axis, prolactin secretion is increased. Despite an increase in prolactin, galactorrhea may not be seen with hypothalamic destruction due to an absence of sex hormones crucial for milk production.[4,18]

Germinomas may have their course complicated by other extracranial manifestations such as genetic abnormalities and metastases. Two genetic diseases seen with germinoma are Klinefelter's syndrome and de Lange's syndrome. Klinefelter's syndrome, originally described in 1942, affects 0.6% of live male neonates and is characterized by gynecomastia, small atrophic testicles, absent spermatogenesis, high urinary excretion of gonadotropins, and eunuchoid habitus.[19] This syndrome has a high association with breast cancer, lymphoma, leukemia, transitional cell carcinoma of the bladder, and prostatic cancer and was first associated with extragonadal germ cell tumors in 1972. Germinoma and choriocarcinoma have both been associated with Klinefelter's syndrome. An alteration in gonadal ridge differentiation leading to malinduction and dyssynchronization of migration of primordial germ cells may explain the association between these maladies.[20-22] De Lange's syndrome was first described in 1933 in two infants with mental retardation, delayed growth and development, short stature, low body weight, bushy eyebrows fused at the midline, long upturned eyelashes, small nose with a low bridge, anteverted nostrils, crescent-shaped mouth, hirsutism, hypoplastic nipples and umbilicus, proximally implanted thumbs, bilateral simian creases, flexion contractions of the elbows, and decreased quantity of pubic hair.[23]

Although intracranial germinomas rarely spread outside the central nervous system, there have been reported cases of distal metastases, mostly from pineal lesions.[24] Because pineal metastases predominate, extracranial metastases from a suprasellar germinoma should suggest that the original tumor contained foci of more malignant germ cell elements.[24] Metastatic sites include lung, kidney, bladder, mediastinum, paratracheal lymph nodes, breast, peritoneum, bone, skin, stomach, small bowel, mesentery, and diaphragm.[24-27] Although peritoneal, pulmonary, and cardiac metastases have been reported in patients without spinal fluid shunting devices, they have been speculated to occur in patients with such systems as a result of seeding from the central nervous system cavity.[25,28,29]

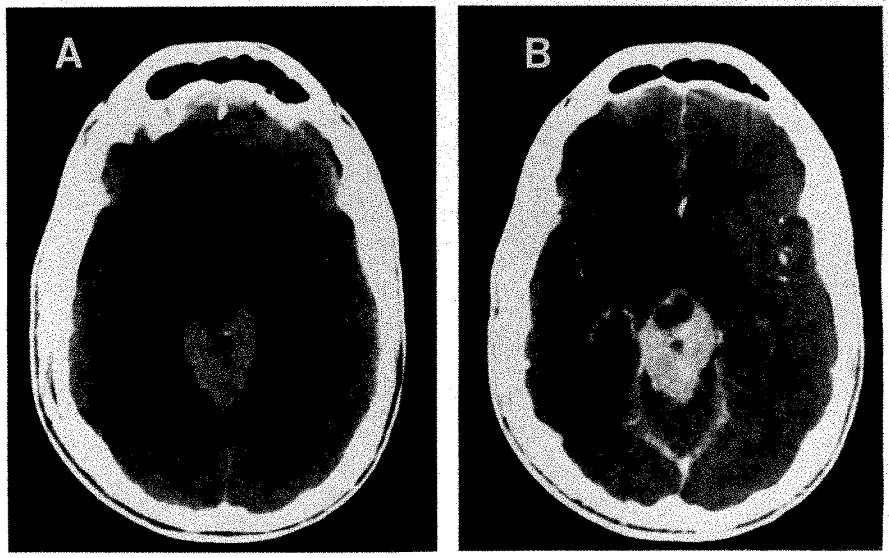

Fig 1.—A, Nonenhanced computed tomographic image of a pineal region germinoma (General Electric Model 9800). Notice increased density in relation to surrounding brain tissue and the presence of intratumoral cysts. B, Contrast-enhanced computed tomographic scan (Isovue 300, Squibb Diagnostics, New Brunswick, NJ).

DIAGNOSIS

Radiologic Evaluation

When the findings of the neurologic examination are abnormal, computed tomography or magnetic resonance imaging is usually the first diagnostic test that is performed. Ganti et al[30] evaluated 16 pineal germinomas by computed tomography and found that 94% percent were denser than brain on unenhanced computed tomographic scan, 88% showed moderate to marked contrast enhancement, 38% showed prominent and slightly enlarged pineal calcification, 63% showed parenchymal calcification with a coarse nodular pattern, and 32% showed meningeal and ependymal seeding. Kageyama et al[31] describe three types of pineal calcifications. Type 1 involves tumor within and around the calcified pineal body. There is no capsule between the mass and the surrounding brain. Type 2 represents several calcified areas that, following radiotherapy, form a single mass. This lesion most likely represents encapsulated tumor growing within the pineal body. Type 3 calcifications appear after radiotherapy. Their pathogenesis remains uncertain; however, they most likely represent intrapineal tumor. Abu-Yousef and Hitchon,[32] in three patients with germinoma, found no evidence of abnormal calcification. Other studies have emphasized the occasional presence of hemorrhage.[33]

While moderate inhomogeneous enhancement after administration of contrast is possible, nonhomogeneous enhancement should suggest another type of lesion.[34,35] An irregular border may represent infiltration.[35] In contrast to germinomas, teratomas are sharply demarcated from the surrounding brain, contain fat, have no significant contrast enhancement, may be cystic, and exhibit linear and nodular calcific deposits on computed tomograms.[30] Cysts may also be found with germinomas and are thought to represent proteinaceous fluid or liquified necrosis (Fig 1).[32] Embryonal cell carcinoma and choriocarcinoma are hyperdense before contrast administration, enhance markedly, and exhibit no abnormal pineal or parenchymal calcification.[30]

Basal ganglia and thalamic germinomas may be associated with ipsilateral cerebral hemiatrophy.[33,36] Wallerian degeneration secondary to the destruction of subcortical structures may be responsible for this wasting.[33] Chang et al[35] state that germinomas in the basal ganglia and thalamus are irregular and demonstrate intratumoral cysts and calcification.

Magnetic resonance imaging represents another method of evaluation. On both long and short repetition time spin echo series in four patients reviewed by Kilgore et al,[37] the signal from germinomas was isodense in comparison with normal brain. The tumor can displace cerebrospinal fluid (CSF) and adjacent structures such as the quadrigeminal plate, sylvian aqueduct, and posterior third ventricle.[37] Germ cell tumors with embryonal cell elements had long T_1- and T_2-weighted signals.[37] Magnetic resonance imaging offers the advantage of easily acquiring images in the coronal and sagittal planes. The disadvantage is the inability to image calcium.

Markers

Cerebrospinal fluid examination for cytologic and marker studies is useful in the evaluation of a patient with a suspected germ cell tumor if samples can be obtained without precipitating herniation. Elevated levels of human chorionic gonadotropin (HCG) and α-fetoprotein (AFP) are more closely correlated with malignant germ cell tumors such as embryonal carcinoma, endodermal sinus tumors (yolk sac tumors), and choriocarcinoma,[2,38-40] with HCG and AFP elevated in the former two and HCG alone elevated in the latter. The level of HCG is only occasionally elevated with germinomas, while the level of AFP is rarely elevated. α-Fetoprotein is usually more specific for highly malignant neoplasms, and HCG is associated with more benign neoplasms, although it can be produced by the most malignant masses. Recently, it has been proposed that absolute levels of AFP should not be used, but rather an AFP index calculated as (CSF/serum AFP)/(CSF/serum albumin), with a value greater than 1.42 indicating local synthesis of AFP in the central nervous system.[41] When present, markers are a useful indicator of tissue type; however, CSF marker levels are not elevated in 10% to 20% of the more malignant germ cell tumors.[38] Measurement of AFP is often unreliable

(1) because there is cross-reactivity of the assay with other CSF proteins, (2) because there is evidence that three types of human AFP exist (one of which may be a normal CSF component), and (3) because many normal individuals and individuals with nonmalignant conditions have elevated levels of AFP.[41] In addition to helping the physician diagnostically, marker levels can be used to evaluate the effectiveness of treatment. Anecdotal reports state that a lack of return of markers to normal levels after treatment indicates a poor prognosis.[38]

Markers other than AFP and HCG have recently been associated with germinomas. The level of angiotensin I–converting enzyme was elevated in the plasma of one patient with a suprasellar germinoma who did not have sarcoid, granulomatous disease, hyperthyroidism, or diabetes, diseases commonly associated with elevated levels of this enzyme. Angiotensin I–converting enzyme was also found in tumor cells obtained by biopsy.[42] Interestingly, an isomeric form of kidney and lung angiotensin I–converting enzyme is present in normal testes and sperm. Another marker, placental alkaline phosphatase was recently found to be associated with germinoma.[5,39] In the past, elevated levels of this enzyme were associated with pregnancy, testicular seminoma, and ovarian, lung, breast, pancreatic, and adrenal cancers.[5,39] Shinoda et al[39] found levels of serum placental alkaline phosphatase that were less than 0.2 IU/mL in patients with teratoma, metastatic choriocarcinoma from the testis, glioma, meningioma and acoustic neurilemoma. Three patients with germinoma had serum levels ranging from 0.52 to 3.78 IU/L, and two had elevated CSF values of 0.83 and 9.83 IU/L (normal, <0.20 IU/L in serum and <0.11 IU/L in CSF). Melatonin has been studied in patients with pineal region tumors. Low melatonin levels are associated with pineal destruction, and high levels suggest the presence of a melatonin-secreting neoplasm. An increase in melatonin has been seen with germinoma. Some argue that such elevation is a consequence of laboratory error.[43]

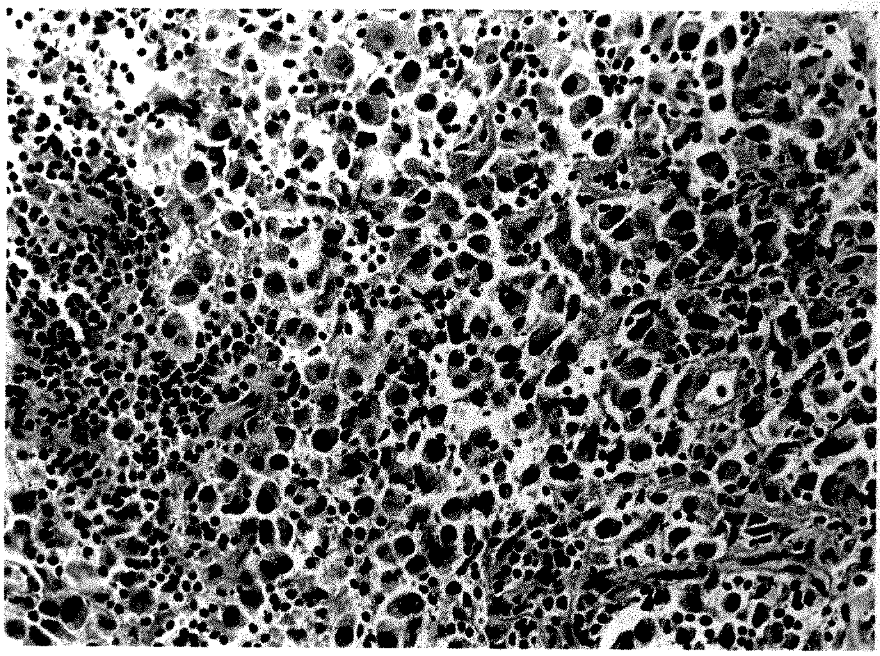

Fig 2.—Microscopic image of a germinoma demonstrating two cell populations. The first consists of large cells with well-defined cell borders, large nuclei, and prominent nucleoli. The second consists of small, round tumor-infiltrating lymphocytes. Occasional mitoses can be seen (hematoxylin-eosin, ×250).

HISTOPATHOLOGIC EXAMINATION

Germinomas characteristically infiltrate locally and spread by dissemination through the craniospinal and subarachnoid spaces. Parenchymal metastases and extradural spread are rare.[40] Grossly, solid tumor tissue can be soft and purplish-gray.

Microscopically, these tumors consist of large polygonal cells surrounded by fibrous connective tissue. Lymphocytic infiltration is most prominent around blood vessels. Cells tend to organize in sheets and lobules and are characterized by large round or oval vesicular nuclei, prominent irregular nucleoli, pale ill-defined cytoplasm, rich stores of glycogen, and coarse or fine granular chromatin.[15,24,27,44,45] Mitotic figures can be present (Fig 2).[24,44]

Ultrastructurally, germinomas display scanty cytoplasm, few organelles, and abundant glycogen. The cytoplasm contains poorly developed Golgi complexes, distorted and aggregated mitochondria, and moderately developed rough and smooth endoplasmic reticulum. Cell membranes are occasionally fused by desmosomes or tight junctions.[15,44] An additional interesting finding is that of intranuclear membranes, structures adjacent to electron-lucent spaces measuring 20 to 100 nm in width and 3 μm in length. Thick layers of chromatin surround these membranes, which are arranged parallel, perpendicular, or oblique to the nuclear envelope. Such structures are sometimes interrupted at regular intervals and occasionally are contiguous with the nuclear envelope over a 20- to 100-nm distance. The significance of these intranuclear membranes is unknown, yet a role in nucleocytoplasmic material exchange has been suggested. They may also be involved with accelerated protein synthesis or abnormal DNA metabolism.[46]

Lymphocytic infiltration of germinomas has been demonstrated by light and electron microscopy. Tumor-infiltrating lymphocytes have been characterized using monoclonal antibodies. In intracranial germinomas, 70% to 80% of tumor-infiltrating lymphocytes were T lymphocytes, and the remainder were B lymphocytes. Cytotoxic/suppressor and helper/inducer T-cell types were intermingled.[47] Cravioto and Dart[48] and Hassoun et al[49] have speculated on the significance of lymphocytes within a tumor. They believe that the activity of tumor-infiltrating lymphocytes may represent a host immunologic response to tumor antigens.

TREATMENT

Past surgical treatment of germinomas by open biopsy or resection was fraught with danger, especially prior to the advent of microsurgical technique. The 30% to 70% morbidity associated with biopsy prompted Torkildsen in 1948 to propose empiric shunting and irradiation for suspicious lesions.[50] More recently, neurosurgeons have relied on other modes of therapy to diagnose and manage this type of germ cell tumor.

Computed tomographic–guided stereotaxis is now an accepted method for obtaining diagnostic tissue. This procedure can provide a sample within 1 to 3 mm of a desired target. However, because the average sample size is 2 to 4 mm in greatest diameter, sampling error can occur when a heterogeneous tumor is encountered.[51] Nevertheless, stereotactic surgery, with a 0% to 0.5% morbidity, provides a safe method of sampling deep intracranial tissues.[50] Linstadt et al[52] followed up 33 patients with germinoma for a median of 5.3 years (range, 0.1 to 27.5 years). At 5 years, all patients with stereotactic biopsy-proved germinomas were alive, while only 73% of the patients who did not undergo biopsy were alive after the same period. An initial incorrect diagnosis was believed to be responsible for this difference, since 66% of those with recurrent disease were found to harbor an ependymoma or a pinealoblastoma. Biopsy, therefore, may increase survival by increasing diagnostic accuracy and as a result allow for the institution of proper therapy.[52]

The extreme radiosensitivity of germinomas has led some to initiate radiation therapy of suspected lesions without a tissue diagnosis. Biopsy studies, however, have shown that only 61% of lesions suspected to be of germ cell origin on the basis of imaging studies will actually be germ cell tumors.[50] Fifteen percent will be of pineal parenchymal origin (pineocytoma or pinealoblastoma), 17% will be gliomas, and 7% will represent other lesions.[50] Tumor regression after a maximum dose of 2000 cGy supports the presence of a germinoma.[34] Tumors that do not respond to such doses may represent mixed tumors, choriocarcinomas, embryonal carcinomas, endodermal sinus tumors, pinealomas, teratomas, and glial tumors. Pinealoblastoma and histiocytosis may respond to radiation treatment.[53]

Radiation regimens for germinoma therapy vary. Most studies recommend 4000 to 6000 cGy to the primary intracranial site[52,54-56] and approximately 3000 cGy to the remainder of the uninvolved brain.[54,56] Recurrence-free rates are reported to be 85% to 100% at 5 to 10 years posttreatment.[50] Local control appears to improve from about 50% with 40 Gy or less to 90% with 50 Gy or more.[50] Some investigators believe that spinal irradiation should be reserved (1) for lesions that demonstrate clear CSF invasion by myelography, cytology, magnetic resonance imaging, or computed tomography; (2) for extensive intracranial disease; (3) for multiple foci of tumor; (4) for ventricular or meningeal seeding; and (5) after tumor spillage at surgery.[50] Cerebrospinal fluid invasion can be expected in 6% to 85% of patients with histologically proved germinomas.[52-55,57] In such situations, dosages vary between 3600 and 4500 cGy.[53,55] Controlled prospective studies have not been performed to determine the value of adjuvant spinal irradiation.[52] Linstadt et al[52] claimed that 8% of their study patients who underwent radiation therapy to the cord developed spinal metastases, while 23% of those who did not undergo radiation therapy developed metastases. In their minds, the 15% benefit provided by radiation therapy did not justify the attendant risks, such as growth retardation and myelitis.[52] Shibamoto et al[56] further complicated the decision-making process by citing their findings in which six patients had positive CSF cultures, did not receive spinal irradiation, and had no spinal involvement over a 6- to 12-year follow-up period. These favorable outcomes may be secondary to decreased viability of free-floating cells or irradiation of cells as they circulate within the CSF and enter an irradiated field.[48] Nevertheless, despite their observations, Shibamoto and colleagues recommend radiation therapy for all individuals with evidence of spinal compartment involvement.

Despite the efficacy of radiation therapy in the treatment of germinomas, chemotherapy has recently been advocated as an adjuvant therapy to decrease the total dose of radiation necessary to induce tumor resolution. This would be especially useful for germinomas in areas where radiation therapy could cause endocrinopathies, cognitive deficits, or other untoward side effects.[58-60] Allen et al[58] described the use of two courses of cyclophosphamide administered as 900 mg/m^2 over 2 days (1800 mg/m^2 total). A complete response to chemotherapy was reinforced by 3000 cGy over 4 weeks, while less than complete resolution was coupled with 5000 cGy over 5 to 6 weeks in 160- to 180-Gy fractions.[58] If the neoplasm was disseminated, spinal irradiation was added. Ninety-one percent of patients had complete resolution and 9% had total regression of the intracranial mass with subsequent positive CSF cytologic studies. Disease-free survival ranged from 23 to 89 months. Complications included neutropenia secondary to marrow toxicity. As a consequence of their findings, Allen and colleagues recommended that the following protocol be carried out when treating any germ cell tumor: (1) biopsy; (2) staging by computed tomography, myelography, CSF markers, and magnetic resonance imaging; (3) chemotherapy; and (4) radiation therapy.

An alternate chemotherapy regimen for the treatment of initial, recurrent, and metastatic germinomas includes bleomycin, cisplatin, and vinblastine sulfate or cisplatin and etoposide.[60-64] The former involves the same chemotherapeutic combination used for testicular tumors. Pharmacokinetic studies have shown significant CSF penetration by cisplatin and bleomycin, but not by vinblastine.[61] Blood-brain barrier penetration is apparently made possible by effects from previous irradiation and/or tumor factors.

As a consequence of improved means of diagnosis and innovative therapies, the current survival rate for patients with germinoma ranges from 66% to 86% after a median follow-up of 5 years or longer.[65] It is these results that make germinomas rewarding tumors to treat, for with proper early diagnosis and appropriate treatment, the patient, who is most often a child, can return to a normal life-style with minimal to little deficit.

Observation

Opercular Cheiro-oral Syndrome

Julien Bogousslavsky, MD; Karin Dizerens, MD; Franco Regli, MD; Paul-André Despland, MD

• Perioral and distal upper limb sensory dysfunction (cheiro-oral syndrome) has classically been attributed to cortical involvement. In previously reported cases of the syndrome, caused by stroke, however, the thalamus or brain stem has been the actual site of the lesion. We have studied two patients with infarct in the superficial middle cerebral artery territory involving the parietal operculum. Sensory involvement was purely subjective in the face, but severe hypoesthesia was present in the distal upper limb, involving mainly position sense, stereognosis, and graphesthesia. Temperature and pain sensation were involved in one patient. These findings correlated with involvement of the lower part of the postcentral gyrus, more caudal parts of the parietal operculum, and underlying white matter. This opercular cheiro-oral syndrome seems more uncommon than faciobrachiocrural hemihypesthesia associated with anterior parietal artery territory infarct. A double supply to the parietal opercular region through branches of the temporal arteries and anterior parietal artery may explain the rarity of cheiro-oral syndrome resulting from hemisphere stroke, because simultaneous and partial compromise to two different pial artery networks is uncommon.

(*Arch Neurol.* 1991;48:658-661)

The "operculum of the insula of Reil," or operculum, refers to the region that surrounds the insula (*operculum* means lid or cover). Since it is formed by part of the frontal, temporal, and parietal gyri, the operculum is usually divided into a frontal operculum, which includes the lower part of the precentral gyrus and of the posterior part of F_3, a temporal operculum, which is the rostral part of the superior temporal gyrus up to Heschl's transverse gyrus, and a parietal operculum, which includes the lower part of the postcentral gyrus and P_1, and may extend to the rostral part of P_2. While an anterior operculum syndrome due to involvement of the frontal operculum has been recognized,[1-4] the neurologic picture associated with damage to the posterior part of the operculum has not been adequately studied. We describe two patients with sensory involvement limited to the perioral region and distal part of the upper limb (cheiro-oral syndrome), in association with parietal opercular infarction.

REPORT OF CASES

CASE 1.—A 63-year-old right-handed male engineer was a cigarette smoker and had untreated hypercholesterolemia. One morning at 2 AM, he suddenly experienced a feeling of disappearance of his right forearm, associated with a decrease of touch sensation without any weakness. At the same time, he experienced tingling in the right side of his mouth. He was admitted to hospital 10 hours later. On neurologic examination, optic fundi, visual acuity, visual fields, and pupil and eye movements were normal. Facial sensation and corneal reflex were symmetrical. A slight decrease in voluntary lower facial contraction was present on the right. There was no dysarthria or dysphagia, and the palate moved symmetrically. The gag reflex was normal. The tongue protruded in the midline. Tactile, pain, and temperature sensation were normal in the face and mouth. Tendon reflexes were symmetrical. The plantar reflexes were flexor. There was a slight distal paresis in the right hand, with decreased finger motility. There was a slight pronator drift with elevation of the right arm. There was a mild difficulty in reaching objects with the right arm, without tremor or asterixis. There was no gait ataxia. Touch, pain, and temperature sensation were abolished in the right forearm. Position sensation of the fingers and wrist was abolished on the right. Stereognosis (recognition of small objects such as keys, coins, or a pin) and graphesthesia (recognition of figures drawn by the examiner on the palm of hand) were also abolished. Vibration (128 Hz) sensation was decreased (4/8) in the right wrist and hand. Neuropsychological examination with a standard battery of tests[5] did not disclose any disturbance. General examination findings were normal. The patient's blood pressure was 150/90 mm Hg. The results of standard blood tests and urinalysis were normal except for an increased cholesterol level (7.3 mmol/L). The electrocardiogram was normal. Extracranial Doppler ultrasounds were normal. Computed tomographic scans of the brain on admission were normal. Magnetic resonance imaging performed after 6 days showed a hyperintense cortical and subcortical area in the left postcentral area at the level of the parietal operculum on T_2-weighted images. The intensity was enhanced after gadolinium injection (Fig 1).

On discharge 11 days after admission, the findings of the neurologic examination had markedly improved. A slight decrease in pain and touch sensation still persisted in the fingers on the right, predominantly in the fourth and fifth fingers. Only a few disturbances in position sensation were still present, but severe stereognostic and graphesthesia disturbances persisted.

CASE 2.—On awakening one morning, a 71-year-old man experienced decrease of touch sensation in his left hand and numbness in the left side of his upper and lower lips.

He had untreated hypertension and insulin-independent diabetes. His right forearm had been amputated 22 years before as a result of a work injury. One year earlier, the patient had experienced transient weakness in the left upper limb. Computed tomography at that time showed a right frontal infarct.

On neurologic examination, the patient was alert and well orientated. Optic fundi,

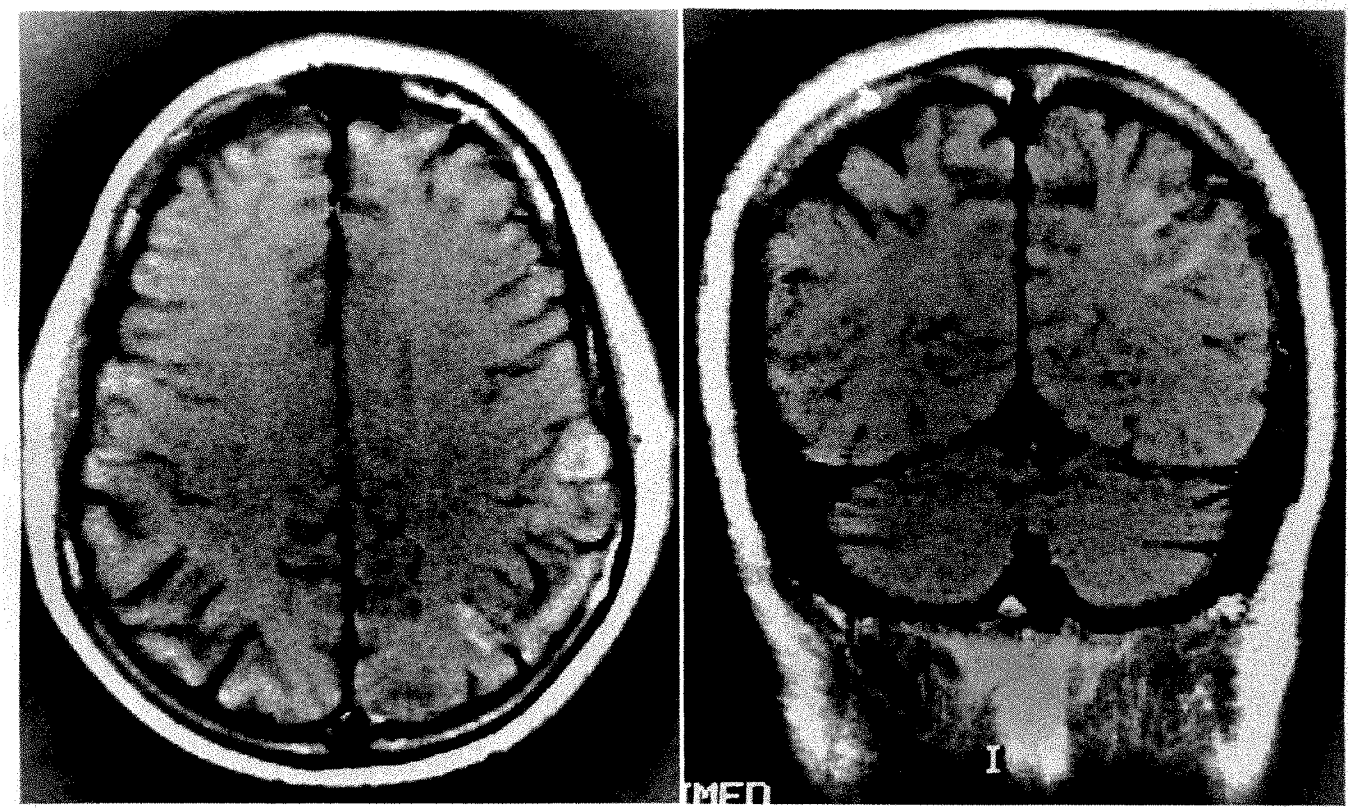

Fig 1.—Patient 1. Magnetic resonance T_1-weighted image after gadolinium injection. Transverse (left) and coronal (right) views show a postcentral infarct extending more caudally within the parietal lobe, involving mainly the cerebral cortex, with little white matter damage. The coronal section (right) shows involvement of the parietal operculum, with damage surrounding the sylvian fissure.

visual acuity, visual fields, and pupil and eye movements were normal. Facial sensation was preserved, with symmetrical corneal reflex. A slight lower facial paresis was present on the right. Tactile, temperature, and pain sensation were normal in the face and mouth. There was no dysphagia and the palate moved symmetrically. The gag reflex was normal. The tongue protruded in the midline. Tendon reflexes were normal and symmetrical. In the limbs, motor strength and tonus were symmetrical and normal. There were elevation and abduction of the left arm, with flexion of the fingers. Fine movements of the fingers (piano playing) were decreased on the left. There was no dysdiadochokinesia or limb dysmetria.

Touch, pain, temperature, and vibration sensation were normal in the four limbs and trunk. Position sensation, stereognosis, and graphesthesia were nearly abolished in the left hand. Sensation was not decreased in the lower limbs, but the patient showed extinction of the left stimulus on simultaneous tactile stimulation of the lower limbs. The results of neuropsychological examination using a standard battery of tests[5] were normal.

The findings of the general examination were normal except for a right carotid bruit. The patient's blood pressure was 219/115 mm Hg. The results of standard blood tests and urinalysis were normal except for a slight anemia (hemoglobin, 126 g/L), an increased cholesterol level (6.2 mmol/L), and slight hyperglycemia (glucose, 6 mmol/L). The electrocardiogram was normal. Doppler ultrasounds and angiography showed a 90% stenosis of the right internal carotid artery. Computed tomography of the brain showed the old right frontal infarct and a recent right postcentral infarct at the level of the parietal operculum (Fig 2).

COMMENT

Both our patients developed cheiro-oral sensory dysfunction in relation to infarct involving the contralateral parietal opercular region. *Cheiro-oral* is a word with Greek-Latin origin, which describes subjective or objective sensory involvement in the peribuccal region and distal part of the upper extremities, mainly the hands and fingers.[6] First described by Sittig[7] in 1914, cheiro-oral sensory involvement, or cheiro-oral syndrome, was thought to be highly suggestive of a cortical lesion in the contralateral hemisphere and corresponded well to the sensory homunculus topography in the cerebral cortex.[6] This assumption was mainly based on the development of paroxysmal cheiro-oral paresthesias, which were likely to be epilectic in patients with tumor or trauma. On the other hand, the role of thalamic involvement was subsequently emphasized in the development of cheiro-oral syndrome,[6] and, in the literature, cheiro-oral syndrome resulting from supratentorial stroke has been reported only in thalamic infarction[8-11] or hemorrhage.[11,12]

The first clinicopathologic study of cheiro-oral syndrome was carried out in 1917 by Schuster,[13] who described a 50-year-old man who experienced paroxysmal tingling in his hand, fingers, and upper lip on the left side, with a slight decrease in position sensation on that side. At autopsy, an "endothelioma" (meningioma) was compressing the lower part of the postcentral gyrus and anterior part of the supramarginal gyrus on the right side; the brain parenchyma itself was not damaged. Seven clinicopathological studies were subsequently published, one involving another patient with a large parietal meningioma,[14] two patients with multiple tuberculomas in the cerebral hemispheres,[15,16] one patient with surgical lesion of the spinothalamic pathways in the midbrain,[17] and three patients with lateral thalamic infarct limited to the ventral posterior nucleus.[8-11] In a review of the literature on cheiro-oral syndrome up to 1965, Haguenau[6] could not find a

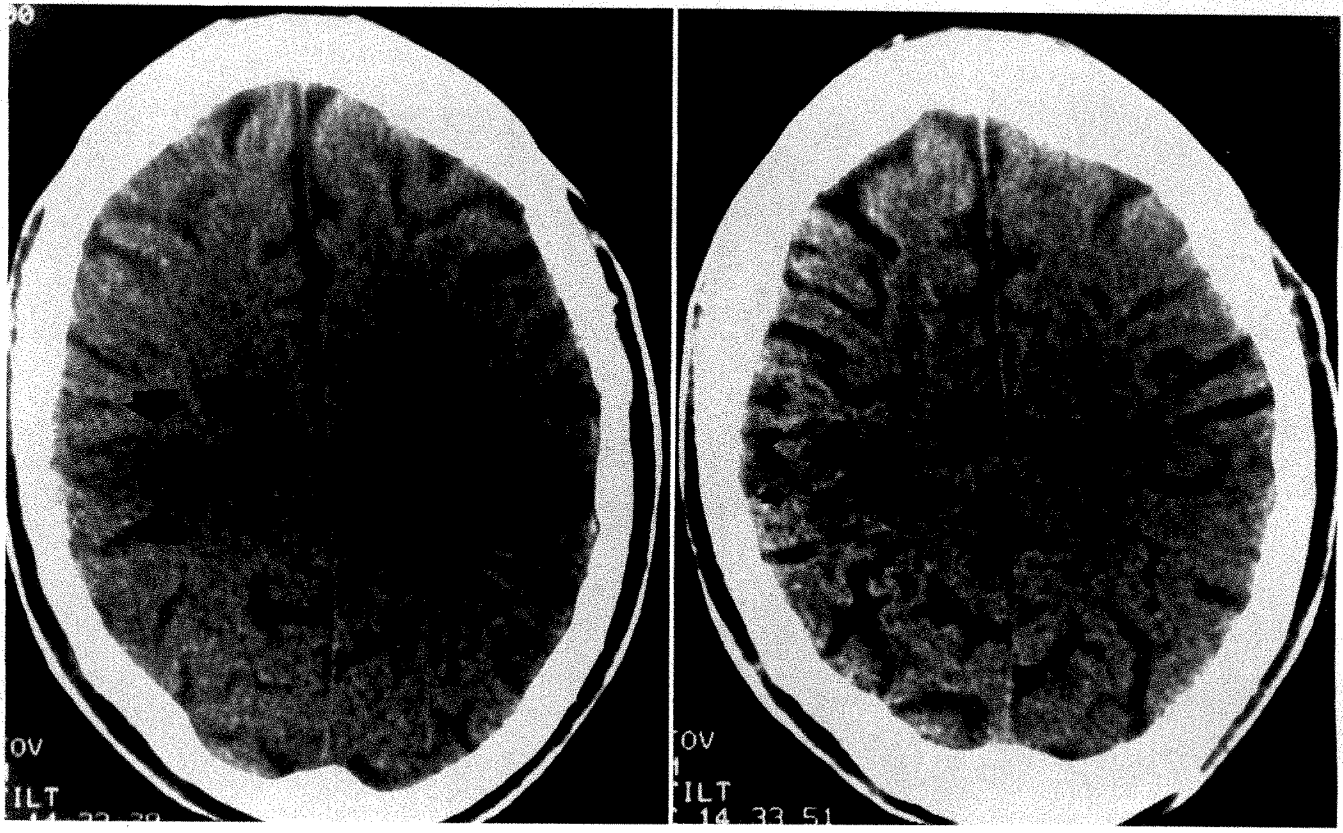

Fig 2.—Patient 2. Computed tomographic scans show a right postcentral infarct (arrows) extending into the underlying white matter.

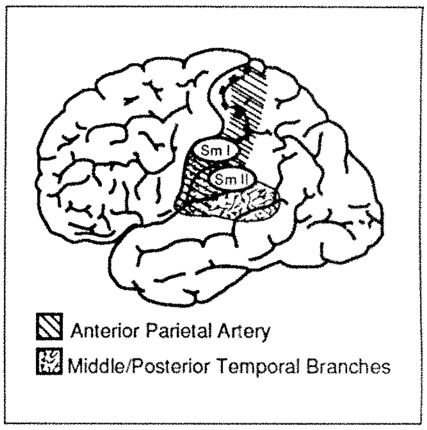
single case of cortical stroke, and he emphasized thalamic involvement. To our knowledge, no patient has been described with cheiro-oral syndrome and stroke involving the cerebral cortex or underlying white matter on computed tomography or magnetic resonance imaging. Apart from thalamic infarction, cheiro-oral syndrome has been associated with pontine infarct,[11] hemorrhage,[18-21] cavernous angioma,[22] and midbrain hemorrhage[23] on computed tomographic and magnetic resonance imaging scans.

Sensory involvement in our patients was purely subjective in the face, but severe hypoesthesia was present in the hands, without any pseudoradicular distribution. This sensory deficit was "cortical" in type, as position sense, stereognosis, and graphesthesia were particularly severely involved (Verger-Dejerine cortical hypesthesia[24,25]). Pain and temperature sensation were involved in the first patient, but spared in the second patient. Vibration sensation was the least affected sensory modality in both patients. Involvement of the postcentral gyrus in the parietal operculum (somatosensory area I) may explain decreased position and discriminative touch sensation, while involvement of the more caudal portion of the parietal operculum and insula (somatosensory area II) may explain decreased pain and temperature sensation (Dejerine-Mouzon hypoesthesia[26]) by damage to the thalamocortical pathways and to the projection area for nocicepsis.[27-29] Disturbed recognition (eg, stereognosis and pain perception) probably relates to more posterior involvement in the lower parietal region.[28] In fact, dissociated sensory disturbance involving proprioception, stereognosis, and graphesthesia may not be specific for cortical damage, as it has also been reported in pure sensory stroke secondary to thalamic infarction.[29]

Another syndrome with hemisensory disturbance has been reported in patients with left anterior parietal artery territory infarction, associating conduction aphasia, mild motor impairment, and marked faciobrachiocrural hypoesthesia mainly involving the elementary modalities of sensation (ie, touch, position, pain, and temperature).[30-35] In the single autopsied case, the infarct involved the postcentral gyrus P_1 and the anterior part of P_2, but it also extended very deeply into the white matter down to the posterior limb of the internal capsule.[30] A pseudothalamic pain syndrome has also been reported in more posterior involvement of the parietal white matter.[36] Involvement limited to the lower part of the postcentral gyrus, posterior parietal operculum, and underlying white matter in our patients may correspond to infarction in the territory of branches from both the anterior parietal artery and the middle and posterior temporal arteries, without more extensive damage to the anterior parietal artery territory (Fig 3). This type of partial superficial middle cerebral artery branch territory infarct seems rather uncommon, as



Sm I

Fig 3.—Lateral view of cerebral hemisphere showing somatosensory areas I (Sm I) and II (Sm II) and arterial supply.

suggested by the absence of previous reports of cheiro-oral syndrome resulting from hemisphere stroke. This rarity is difficult to explain, but may be related to the vascular anatomy of the posterior opercular region, which has a double vascular supply through branches from the temporal arteries and anterior parietal artery.[37-41]

Our findings highlight the nonspecificity of cheiro-oral sensory disturbance in acute stroke. They also provide evidence for partial middle cerebral artery territory infarction limited to the posterior opercular region.

Professional Opportunities

NEUROLOGIST: Excellent opportunity for board-certified/board-eligible neurologists to join two existing neurologists in a stimulating, busy practice. Marquette General Hospital is a 321-bed regional referral center, with a comprehensive neurophysiology department and state-of-the-art technology that includes magnetic resonance imaging and CT scanning, and a hospital-based family practice residency. Medical students from Michigan State University's College of Human Medicine are regularly assigned to the hospital and offer an opportunity for teaching. Marquette General Hospital and its medical staff are committed to building a center of excellence in the neurosciences and have the necessary financial resources. The development of these services will require the leadership and cooperation of physicians in the field of neurology, neurosurgery, psychiatry, physical medicine and rehabilitation. Salaried and private practice positions are available. If this special opportunity is of interest to you, please send CV to: Robert J. Raica, Marquette General Hospital, 420 West Magnetic Street, Marquette, MI 49855.

NEUROLOGIST

Neurologist, board-eligible or board-certified, with EEG, EMG, EP and neuro-CT needed to join an adult neurologist in a 32-physician multi-specialty clinic, 100 miles southeast of St. Louis. Population 28,000 plus 25,000 Southern Illinois University students.

Opportunity exists for affiliation with SIU Medical School. No capital investment. Flexible compensation package with generous fringe benefits including health and disability, vacation, CME leave, and profit sharing retirement plan.

Contact:
William R. Hamilton,
CEO/Medical Director
CARBONDALE CLINIC
2601 West Main
Carbondale, IL 62901 ◆ (618) 549-5361

NEUROLOGIST to join dynamic, midwest neurology group. This very busy practice is seeking an energetic neurologist with a strong interest in the clinical care of patients. This opportunity is located in a desirable, midwestern community abundant in cultural and sporting activities. The practice has a well-equipped radiology department with MRI and CT, and also, neurophysiology and neuropsychology departments. The appropriate candidate must be energetic, pleasant, BC/BE, with EMG experience. Please send curriculum vitae to: Box #814, c/o AON.

CHARLOTTE, NORTH CAROLINA: High quality group of six neurologists, all of whom are subspecialized, seeks to add a well-trained specialist. Contact: Mike Kaufman, MD, 126 Cottage Place, Charlotte, NC 28207. Or call: (704) 334-7311.

FLORIDA'S CENTRAL EAST COAST—Adult neurologist with EMG training wanted to join group of eight neurologists. We live an a high tech, beachside community with great schools and affordable housing. Please send CV to: Search Committee, P.O. Box 693, Melbourne, FL 32902.

Professional Opportunities

EXCELLENT OPPORTUNITY for BC/BE neurologist to join 80-physician, comprehensive, multispecialty group in San Francisco Bay Area. Large, varied referral base from pediatrics, IM, FP, and surgery. EMG/NCV, EEG, evoked response testing, CT, MRI, radiology support all available on site. Opportunity to interface with sepcialists of all types including neurosurgeons. Major university teaching affiliation encouraged and possible. Close proximity to 400-bed full service, modern hospital serving population of 300,000. Competitive guaranteed salary with bonus productivity plan for initial 18 months leading to partnership track. Extensive benefit package including housing incentives. Unique cultural, recreational and educational opportunities. Send CV to: Gary D. Zweig, MD, Recruitment Chairman, Sunnyvale Medical Clinic, P.O. Box 3496, Sunnyvale, CA 94088-3496.

KANSAS — Board-certified, board-eligible neurologist to join child neurologist in rebuilding a three-person practice in the largest city in Kansas. Three large, well-equipped hospitals available for resident and undergraduate medical education. Located in clean, progressive community described as the franchise capital of the country. Competitive salary and benefits available. Send CV to: Richard C. Gilmartin, MD, 2620 East Central, Wichita, KS 67214.

CHICAGO — BC/BE neurologist to join existing practice. Highly motivated individual with strong clinical skills and EMG/EEG expertise needed to join two busy neurologists. Very strong medical school affiliation with teaching responsibilities for neurology and internal medicine, residents and medical students. Large referral base. Excellent benefit package. Please provide CV. Please contact: Box #818, c/o AON.

PEDIATRIC NEUROLOGY — Unusual opportunity to join premier group in medium-sized community in the northern midwest. Seeking BC/BP pediatric neurologist to join three adult practitioners. Practice in place. Excellent financial package available leading to partnership. Telephone or write: Mary Frances Lyons, MD at (800) 765-3055; Local (314) 862-2345; c/o Cejka & Co., 222 South Central, Suite 700, St. Louis, MO 63105. FAX: (314) 726-3009.

MAUI ORTHOPEDIC and Sports Medicine seeks neurologist to establish independent practice. Contact: William Gfeller, 450 Hookahi Street, Wailuku, Maui, HI 96793. (808) 244-5541.

ATTENTION PHYSICIAN RECRUITERS. The "Classified Advertising" sections now in all nine AMA Specialty Journals target the physician you want. These highly visible sections put your message in the hands of every specialist that qualifies for your professional opportunity, every month. To place the ad of your choice, any size, call toll free: (800) 237-9851; or in Florida (800) 553-8288.

NEUROLOGIST — BE/BC to join thriving practice in suburban Pittsburgh. Excellent opportunity with two community hospitals. Comprehensive diagnostic laboratory facilities adjacent to main office. Interest in EMG/EEG desirable. Competitive salary, leading to partnership. Convenient to excellent schools and quality affordable housing. Contact: Kelly McMahon, Daniel Stern & Associates, 211 North Whitfield Street, Suite 240, Pittsburgh, PA 15206. (800) 438-2476.

PLEASE NOTE—Address replies to box number ads as follows: Box number ______, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

Neurologist

The Mason City Clinic is a progressive multi-specialty clinic in the Heartland.

We are looking for a neurologist to join our very busy practice. Small-town security within two hours of Minneappolis and Des Moines.

MRI, CT, sleep lab, EEG, EMG, neurosurgery, cardiac surgery, orthopedic surgery, cancer center, GI lab, and ENT capabilities.

Excellent salary and benefits.

Submit CV to:

Ralph A. Wolf, Administrator
300 N. Eisenhower Avenue
Mason City, IA 50401
(515) 423-2435

NEUROLOGIST NEEDED:

NEW ORLEANS, LA.
NASHVILLE, TN.

Practice opportunities exist in suburban communities of New Orleans and Nashville for board-certified or board-admissible, General Adult Neurologist. Practice offers clinical and hospital setting with competitive salary, practice establishment package, and early partnership in excellent family oriented communities.

Send curriculum vitae to:

Dennis Bottomley
Physician Placement Service of America
330 Franklin Road
Brentwood, TN 37024
Or call: (800) 359-7421
FAX: (615) 395-4764

Professional Opportunities

SOUTHEAST COAST — The Neuroscience Center of a 190-bed regional medical center is seeking a BC/BE neurologist to join in close association with their existing neurosurgeons. Exceptional medical facilities and neurological services including EEG/EMG, EP, CT, MRI. Excellent income guarantee plus benefits — large drawing area provides for outstanding potential. Located ninety minutes from one of this country's premiere seaside resorts, this dynamic community offers a quality lifestyle. Call Mark Prosperi at (800) 776-5776 for more details or send CV to: Cejka & Co., 1034 South Brentwood Boulevard, St. Louis, MO 63117.

SOUTHEAST COAST — Pediatric Neurologist: Excellent quality of life available in Savannah-Hilton Head Area, site of the 1996 Olympic Games sailing events. Outstanding recreational opportunities, nation's largest urban Historic District, and superb symphony are among the attractions of living here. A well-trained, personable neurologist with special competence in child neurology is needed for a busy practice, currently consisting of two adult neurologists and one neurologist doing adult and child neurology, all with strong academic backgrounds. CT, EEG, EMG and physical therapy are available in-office with large hospital practice available in three hospitals, including a major regional teaching hospital, affiliated with the Medical College of Georgia. First year guarantee is $80,000 plus bonus, leading to full partnership after two years. Earnings potential, availability of strong multi-specialty support, and opportunities for teaching are extraordinary. If interested contact: Randy Wellman, Office Manager, Savannah Neurological Associates, PC, P.O. Box 23059, Savannah, GA 31403. (912) 354-8151.

ADULT NEUROLOGIST to associate with two separate, busy solo neurologists. Practices are referral based, with two separate offices and three voluntary hospitals. Successful candidate would be expected to develop a separate solo, but collaborative practice. Established physicians would expect to provide substantial support for beginning physician. Opportunity would provide for cross coverage and joint venturing of facilities. Successful candidate should have excellent clinical skills. The medical community has excellent neurophysiology, neuroradiology, and neurosurgery. Located in a medium size city with both excellent living conditions and an extremely solid economic base. Please contact: Jeffrey A. Ribner, MD, 503 Plaza Drive, Vestal, NY 13850. (607) 729-1521 or Robert R. Taylor, Jr., MD, 269 Riverside Drive, Johnson City, NY 13790. (607) 798-7143.

SEEKING ENERGETIC BE/BC NEUROLOGIST to join three adults and one child neurologist. Prefer someone with interest in general neurology and special interest and training in any of the following areas: sleep medicine, neurophysiology testing, neuro-rehabilitation, pain, or neuro-intensive care. Excellent medical community with all of the supportive consultants and technology. Send CV to: Neurological Associates of Grand Rapids, PC, 2855 Michigan Street, Northeast, Grand Rapids, MI 49506.

NEUROLOGIST — BC/BE, full- or part-time, for exanding San Francisco Bay area. Private practice with emphasis on clinical occupational neurology and med-legal evaluations. Expertise in EMG, EEG and EP desired. Excellent reputation, referral base, facilities and support staff. Unique income opportunity. Submit CV and letter stating professional goals, and availability to: Personnel, 2040 Polk Street, Box 337, San Francisco, CA 94109.

NEUROLOGIST TO DIRECT Movement Disorders Program — The Cleveland Clnic Department of Neurology is seeking a BE/BC neurologist to direct and develop a major Movement Disorders Program. Fellowship training in movement disorders is highly desirable, as is experience with clinical research trials especially related to Parkinson's disease. This is an outstanding opportunity to join a premier clinical neurology group with a strong commitment to education and research. Interested individuals should send CV and three references to: Anthony J. Furlan, MD, Head, Section of Adult Neurology or Hans Luders, MD, PhD, Chairman, Department of Neurology, The Cleveland Clinic Foundation, One Clinic Center, Cleveland, OH 44195. The Cleveland Clinic Foundation is an equal opportunity/affirmative action employer.

Professional Opportunities

FOOTHILLS OF MOUNTAINS where Tennessee, North Carolina and Virginia meet. Busy general neurology practice with opportunity to develop subspecialty interest in epilepsy, sleep, pediatrics, trauma or rehab. Plentiful EMGs and EEGs. Appointment at state university medical school. Community boasts award winning schools, affluent patient base, boating, snow-skiing, camping and the arts. Call Daine Safner at: (800) 765-3055. Or send CV to: 222 South Central, Suite 700, St. Louis, MO 63105.

NEUROLOGIST — Beautiful Durango, Colorado is recruiting a BC/BE neurologist. Mercy Medical Center is an extremely progressive and active 100-bed facility and is doing well financially and growing — primarily due to an excellent staff of 90 physicians and a decent economy. Durango is located in southwestern Colorado, with an abundance of outdoor recreation (skiing, fishing, hunting, bicycling) excellent restaurants, an excellent local 4-year college, great weather and excellent schools! For more information about this excellent practice opportunity, mail CV or call: Bob Conrad, Vice President, Mercy Medical Center, 375 East Park Avenue, Durango, CO 81301. (303) 247-3804.

The Division of Movement Disorders in the Department of Neurology of Henry Ford Hospital is seeking a second neurologist to join the Gossett Parkinson's Disease Center.

The candidate should have fellowship training in movement disorders. The position will include half-time for research activities. The department is large, committed to academic excellence, and offers excellent research opportunities in NMR spectroscopy, pharmacology, epidemiology, neuropsychology and basic neurobiology. Candidates should be capable of developing a research program, partly collaborating with others in the center. Competitive salary and benefits are offered, commensurate with experience.

Send CV and two references to:

Jay M. Gorell, MD, Director
Division of Movement Disorders and
Gossett Parkinson's Disease Center
Department of Neurology
Henry Ford Hospital
2799 West Grand Boulevard
Detroit, Michigan 48202.

Henry Ford Hospital is an equal opportunity employer.

EXCELLENT OPPORTUNITY for BC/BE neurologist to join 80-physician comprehensive, multi-specialty group in San Francisco Bay Area. Large, varied referral base from Pediatrics, IM, FP, and Surgery. EMG/NCV, EEG, Evoked Response Testing, CT, MRI, Radiology support all available on site. Opportunity to interface with specialists of all types including neurosurgeons. Major university teaching affiliation encouraged and possible. Close proximity to 400-bed full service, modern hospital serving population of 300,000. Comeptitive guaranteed salary with bonus productivity plan for initial 18 months leading to partnership track. Extensive benefit package including housing incentives. Unique cultural, recrational and educational opportunities. Send CV to: Gary D. Zweig, MD, Recruitment Chairman, Sunnyvale Medical Clinic, P.O. Box 3496, Sunnyvale, CA 94088-3496.

BC/BE NEUROLOGIST — Exceptional opportunity to establish a practice in northwest Denver suburb. No investment required. Strong referral base. Opportunity to affiliate with two busy neurologists with office located adjacent to beautiful 400-bed hospital with state-of-the-art technology. Excellent opportunity for subspecialty trained with a strong interest in the clinical care of patients. Send CV to: Box #819, c/o AON.

PLEASE NOTE—Address replies to box number ads as follows: Box number ______, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

Professional Opportunities

NEUROLOGIST — BOARD-CERTIFIED or -eligible neurologist with California license needed to join a prestigious Worker's Compensation clinic for patient evaluation and follow-up and EMG/NCS testing. For further information contact Christine Benson at: (213) 277-2929. Or send CV to: 1125 South Beverly Drive, #601, Los Angeles, CA 90035.

ROCKY MOUNTAINS

Third neurologist sought for very busy practice in city of 60,000. Group includes other medicine subspecialists. Call one in three. Excellent clinic and hospital facilities. EEG and EMG in clinic. No other neurologists in community.

Great lifestyle location for skiing, hiking, fishing, camping, etc. Excellent school system, low taxes.

For additional information about this excellent opportunity, call Greg Peterson at: (800) 669-4804 or (913) 599-4804.

THE PETERSON GROUP
8700 Monrovia, Suite 302
Shawnee Mission, KS 66215

NEUROLOGIST: BC/BE neurologist to replace retiring partner in established four-person department associated with 106-physician multi-specialty clinic located in beautiful northwest Arkansas. Holt-Krock Clinic is the 33rd largest freestanding clinic in the nation, serving a patient base of 400,000 in Arkansas and Oklahoma. Full range of electrical studies offered with EEG, EMG, evoked response, and cervical vascular ultrasound procedures. We offer a guaranteed salary with full partnership in 2 to 2½ years, plus excellent fringe benefits. 680-bed hospital and new rehab hospital two blocks from main clinic. For details regarding this opportunity, send letter and CV to: Mrs. Josephine Decker, Associate Administrator, Holt-Krock Clinic, 1500 Dodson Avenue, Fort Smith, AR 72901. (501) 782-2071.

EXPANDING, DYNAMIC ADULT neurology practice — BC/BE neurologist to join rapidly growing office and multi-hospital practice in New Jersey — 15 minutes from Manhattan. Candidate must be energetic and personable. EMG, EEG experience preferred. Send CV to: Joseph Sobelman, MD, 834 Avenue C, Bayonne, NJ 07002.

Faculty Positions

LOYOLA UNIVERSITY Chicago Stritch School of Medicine, Department of Neurology invites applications for two positions at the Assistant Professor level. Applicants should be board-eligible or -certified in neurology and have subspecialty expertise in either epilepsy, movement disorders, cerebrovascular diseases, behavioral or geriatric neurology. Preference will be given to candidates with clinical research interests. Send CV to: Gastone Celesia, MD, Chairman, Neurology Department, Loyola University Chicago, 2160 South First Avenue, Chicago, IL 60153. Loyola University Chicago is an equal opportunity/affirmative action employer.

NEUROLOGIST BC/BE: The Texas College of Osteopathic Medicine is recruiting an academically oriented neurologist with interest in clinical neurology, teaching and research. Faculty appointment provides competitive salary with excellent fringe benefits. Please send curriculum vitae and letter of inquiry to William E. McIntosh, DO, Associate Professor of Medicine/Neurology, Texas College of Osteopathic Medicine, 3500 Camp Bowie Boulevard, Fort Worth, TX 76107. TCOM is an affirmative action/equal opportunity employer.

FULL-TIME TENURE-TRACK faculty opportunities available for BC/BE neurologists with dementia, EMG/neuromuscular diseases and cerebrovascular disease expertise. Successful applicants will be provided laboratory space and support in a dynamic growing department, take an active role in the Creighton-Nebraska neurology training program and be afforded ample research and clinical collaborative opportunities for career advancement. Creighton is an established university and medical center with expanding and diverse facilities, including a new PET Center. Send inquiries to: John M. Bertoni, MD, PhD, Professor and Chairman, Department of Neurology, 601 North 30th Street, Suite 2342, Omaha, NE 68131. EOE.

Faculty Positions

THE UNIVERSITY OF Mississippi Medical Center Department of Neurology invites applications for position of Assistant Professor from board-certified individuals with strong research, clinical and teaching skills. Persons with expertise in neuro-oncology, vascular disease, and epilepsy are especially being sought. Please submit a letter of intent, curriculum vitae, and letters of recommendation from three physicians to: Dr. James J. Corbett, Chairman, Department of Neurology, The University of Mississippi Medical Center, Jackson, MS 39216-4505. The University of Mississippi Medical Center is an equal opportunity employer. M/F/H/V.

ACADEMIC NEUROLOGIST: University Colorado School Medicine, Denver. Full-time faculty position based at Denver General Hospital. Responsibilities include inpatient attending, outpatient clinics, training neurology residents and teaching medical students clinical neurology. Clinical research and EMG experience desirable, but not required. CV: Donald Gilden, MD, Chairman, Department Neurology, 4200 East 9th Avenue, Denver, CO 80262. AA/EOE.

Residencies

PGY-III — University of South Alabama Medical Center invites applications for a PGY-III position in Neurology beginning July 1, 1991. Reply to: Paul Dyken, MD, Professor and Chairman, Department of Neurology, 2451 Fillingim Street, Mobile, AL 36617. Telephone: (205) 471-5801.

ADULT NEUROLOGY RESIDENCY PGY-IV position available at the University of Colorado School of Medicine for July, 1991. Contact: James P. Kelly, MA, MD, Director of Resident Selection, Department of Neurology, UCHSC B-183, 4200 East Ninth Avenue, Denver, CO 80262. (303) 270-8760.

CHILD NEUROLOGY RESIDENCY. The Department of Neurology at the Medical College of Wisconsin has a first year position available for July 1, 1992, in a fully accredited three-year training program at the new Children's Hospital of Wisconsin. There are five full-time pediatric neurologists conducting a strong general clinical neurology program with programs of special emphasis in both clinical and basic science in oncology, epilepsy, neurobehavior, and neuromuscular disorders. Candidates should have two years of pediatric training in an ACGME-accredited program. Contact: Richard J. Konkol, MD, PhD, Chief, Section of Pediatric Neurology, 8701 Watertown Plank Road, Milwaukee, WI 53226. Telephone (414) 266-4090, or Eric Maas, MD, Neurology Residency Director, Froedtert Memorial Lutheran Hospital, 9200 West Wisconsin Avenue, Milwaukee, WI 53226.

Miscellaneous

WRITE BRIEF REVIEWS on topics in neurology for $500-$1,000. Respond with CV to: Dr. S. Demeter, Arbor Publishing Corp., 333 Metro Park, Suite N-208, Rochester, NY 14623.

Positions Wanted

COMPHEALTH PROVIDES the finest locum tenens (Temporary physician staffing) service nationwide. Each CompHealth neurologist is carefully screened and referenced ensuring you competent, reliable coverage. Have your practice covered or join us and cover other practices. Call CompHealth, the nation's oldest and largest supplier of temporary physician staffing services, at: (800) 328-3043 toll-free. Or write: 4021 South 700 East, Salt Lake City, UT 84107.

Directors Wanted

DIRECTOR, CLINICAL EEG/EP laboratory with an appointment in Department of Neurology, Harvard Medical School, is sought by the Neurology Division, Brigham and Women's Hospital, Boston. The successful candidate will direct the clinical, investigative and teaching aspects of the EEG and EP laboratory. Applicants should be board-certified neurologists with demonstrated facility in neurophysiology. Clinical skill and laboratory expertise are equally important aspects of the position. Please send inquiries and CV to: Martin A. Samuels, MD, Brigham and Women's Hospital, 75 Francis Street, Boston, MA 02115. Brigham and Women's Hospital and Harvard Medical School are equal opportunity employers.

DIRECTOR, Neurology-Neurosurgery Intensive Care Unit with an appointment in Department of Neurology, Harvard Medical School, is sought by the Neurology Division, Brigham and Women's Hospital, Boston. The successful candidate will direct the clinical, investigative and teaching aspects of Neuro-ICU. Applicants should be board-certified in Neurology and Internal Medicine with demonstrated facility in organizing and operating a Neuro-ICU. Clinical skill and clinical research facility are equally important aspects of the position. Please send inquiries and CV to: Martin A. Samuels, MD, Brigham and Women's Hospital, 75 Francis Street, Boston, MA 02115. Brigham and Women's Hospital and Harvard Medical School are equal opportunity employers.

Associate Clinical Directors

Synergen, Inc., a growing biotechnology company in Boulder, Colorado, seeks experienced Associate Clinical Directors for the clinical evaluation of several innovative recombinant DNA protein therapies for wound healing, inflammation, sepsis, pulmonary and neurological diseases. As part of the new clinical team, these two new positions will work with the Medical Director to plan clinical research projects and to design, monitor, evaluate and report clinical trials.

Requirements include M.D. degree with specialty training in neurology for one position. For the other position requirements include M.D. degree with specialty training in pediatrics or internal medicine with subspecialty training in pulmonology. Approximately 2-3 years' experience in pharmaceutical industry positions that have provided a thorough background in the design and execution of clinical studies (Phases I through III) required. The successful candidates should have the ability to develop, execute and manage a fully integrated clinical trial program.

Synergen offers competitive salaries, generous benefits, and the financial stability required for future development. Please send a resume to: **MXB, Four Embarcadero Center, Ste. 3570, San Francisco, CA 94111.** We are an Equal Opportunity Employer.

SYNERGEN

Dilantin® Kapseals®
(extended phenytoin sodium capsules, USP)

Dilantin® KAPSEALS® (Extended Phenytoin Sodium Capsules, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows.

INDICATIONS AND USAGE: Dilantin is indicated for the control of generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and prevention and treatment of seizures occurring during or following neurosurgery.

Phenytoin serum level determinations may be necessary for optimal dosage adjustments (see Dosage and Administration and Clinical Pharmacology in the full prescribing information).

CONTRAINDICATIONS: Phenytoin is contraindicated in those patients who are hypersensitive to phenytoin or other hydantoins.

WARNINGS: Abrupt withdrawal of phenytoin in epileptic patients may precipitate status epilepticus. When, in the judgment of the clinician, the need for dosage reduction, discontinuation, or substitution of alternative antiepileptic medication arises, this should be done gradually. However, in the event of an allergic or hypersensitivity reaction, rapid substitution of alternative therapy may be necessary. In this case, alternative therapy should be an antiepileptic drug not belonging to the hydantoin chemical class.

There have been a number of reports suggesting a relationship between phenytoin and the development of lymphadenopathy (local or generalized) including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin's Disease. Although a cause and effect relationship has not been established, the occurrence of lymphadenopathy indicates the need to differentiate such a condition from other types of lymph node pathology. Lymph node involvement may occur with or without symptoms and signs resembling serum sickness, eg, fever, rash and liver involvement.

In all cases of lymphadenopathy, follow-up observation for an extended period is indicated and every effort should be made to achieve seizure control using alternative antiepileptic drugs.

Acute alcoholic intake may increase phenytoin serum levels while chronic alcoholic use may decrease serum levels.

In view of isolated reports associating phenytoin with exacerbation of porphyria, caution should be exercised in using this medication in patients suffering from this disease.

Usage in Pregnancy: A number of reports suggests an association between the use of antiepileptic drugs by women with epilepsy and a higher incidence of birth defects in children born to these women. Data are more extensive with respect to phenytoin and phenobarbital, but these are also the most commonly prescribed antiepileptic drugs; less systematic or anecdotal reports suggest a possible similar association with the use of all known antiepileptic drugs.

The reports suggesting a higher incidence of birth defects in children of drug-treated epileptic women cannot be regarded as adequate to prove a definite cause and effect relationship. There are intrinsic methodological problems in obtaining adequate data on drug teratogenicity in humans; genetic factors or the epileptic condition itself may be more important than drug therapy in leading to birth defects. The great majority of mothers on antiepileptic medication deliver normal infants. It is important to note that antiepileptic drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures, because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus. The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

In addition to the reports of increased incidence of congenital malformation, such as cleft lip/palate and heart malformations, in children of women receiving phenytoin and other antiepileptic drugs, there have more recently been reports of a fetal hydantoin syndrome. This consists of prenatal growth deficiency, microcephaly and mental deficiency in children born to mothers who have received phenytoin, barbiturates, alcohol, or trimethadione. However, these features are all interrelated and are frequently associated with intrauterine growth retardation from other causes.

There have been isolated reports of malignancies, including neuroblastoma, in children whose mothers received phenytoin during pregnancy.

An increase in seizure frequency during pregnancy occurs in a high proportion of patients, because of altered phenytoin absorption or metabolism. Periodic measurement of serum phenytoin levels is particularly valuable in the management of a pregnant epileptic patient as a guide to an appropriate adjustment of dosage. However, postpartum restoration of the original dosage will probably be indicated.

Neonatal coagulation defects have been reported within the first 24 hours in babies born to epileptic mothers receiving phenobarbital and/or phenytoin. Vitamin K has been shown to prevent or correct this defect and has been recommended to be given to the mother before delivery and to the neonate after birth.

PRECAUTIONS: General: The liver is the chief site of biotransformation of phenytoin; patients with impaired liver function, elderly patients, or those who are gravely ill may show early signs of toxicity.

A small percentage of individuals who have been treated with phenytoin has been shown to metabolize the drug slowly. Slow metabolism may be due to limited enzyme availability and lack of induction; it appears to be genetically determined.

Phenytoin should be discontinued if a skin rash appears (see "Warnings" section regarding drug discontinuation). If the rash is exfoliative, purpuric, or bullous or if lupus erythematosus, Stevens-Johnson syndrome, or toxic epidermal necrolysis is suspected, use of this drug should not be resumed and alternative therapy should be considered. (See Adverse Reactions.) If the rash is of a milder type (measles-like or scarlatiniform), therapy may be resumed after the rash has completely disappeared. If the rash recurs upon reinstitution of therapy, further phenytoin medication is contraindicated.

Phenytoin and other hydantoins are contraindicated in patients who have experienced phenytoin hypersensitivity. Additionally, caution should be exercised if using structurally similar (eg, barbiturates, succinimides, oxazolidinediones and other related compounds) in these same patients.

Hyperglycemia, resulting from the drug's inhibitory effects on insulin release, has been reported. Phenytoin may also raise the serum glucose level in diabetic patients.

Osteomalacia has been associated with phenytoin therapy and is considered to be due to phenytoin's interference with Vitamin D metabolism.

Phenytoin is not indicated for seizures due to hypoglycemic or other metabolic causes. Appropriate diagnostic procedures should be performed as indicated.

Phenytoin is not effective for absence (petit mal) seizures. If tonic-clonic (grand mal) and absence (petit mal) seizures are present, combined drug therapy is needed.

Serum levels of phenytoin sustained above the optimal range may produce confusional states
referred to as "delirium," "psychosis," or "encephalopathy," o
dysfunction. Accordingly, at the first sign of acute toxicity, plasma
reduction of phenytoin therapy is indicated if plasma levels are e
termination is recommended. (See Warnings.)

Information for Patients: Patients taking phenytoin should be
adhering strictly to the prescribed dosage regimen, and of inform
condition in which it is not possible to take the drug orally as p

Patients should also be cautioned on the use of other drugs or
seeking the physician's advice.

Patients should be instructed to call their physician if skin ras

The importance of good dental hygiene should be stres
development of gingival hyperplasia and its complications.

Do not use capsules which are discolored.

Laboratory Tests: Phenytoin serum level determinations may b
dosage adjustments.

Drug Interactions: There are many drugs which may increase
which phenytoin may affect. Serum level determinations for p
when possible drug interactions are suspected. The most comm
are listed below: 1. Drugs which may increase phenytoin seru
intake, amiodarone, chloramphenicol, chlordiazepoxide, diaz
estrogens, H_2-antagonists, halothane, isoniazid, methyl
phenylbutazone, salicylates, succinimides, sulfonamides, tolb

2. Drugs which may decrease phenytoin levels include: carbam
reserpine, and sucralfate. Moban® brand of molindone hydroc
which interfere with the absorption of phenytoin. Ingestion ti
preparations containing calcium should be staggered in patients
to prevent absorption problems.

3. Drugs which may either increase or decrease phenytoin seru
sodium valproate, and valproic acid. Similarly, the effect of pheny
acid and sodium valproate serum levels is unpredictable.

4. Although not a true drug interaction, tricyclic antidepressa
susceptible patients and phenytoin dosage may need to be adj

As rare as a seizure on Dilantin®(extended phenytoin sodium capsules, USP) 100 mg

For as many as 86% of patients, seizures occur only once in a blue moon- if at all—once Dilantin monotherapy is under way.[1]

That fact holds true for partial, complex partial, generalized tonic-clonic seizures, and status epilepticus.

And it's achieved *without* significan cognitive impairment at therapeutic drug levels (10 to 20 μg/mL),[2] often wi once-daily therapy (Dilantin® Kapseals® which enhances compliance.

What you demand, Dilantin does—for millions of patients every day.

That's why Dilantin remains a drug of choice.

And that's why most patients on Dilantin will wait a long, long time to see another seizure.

Dilantin®

nce in a blue moon" describes the phenomenon in which he moon appears as a brilliant blue. Seen worldwide following he volcanic eruption of Krakatoa in 1883, the blue moon occurs nly when atmospheric cloud droplets, each less than 5 μm in iameter, form in abundance—an exceedingly rare event.[3]

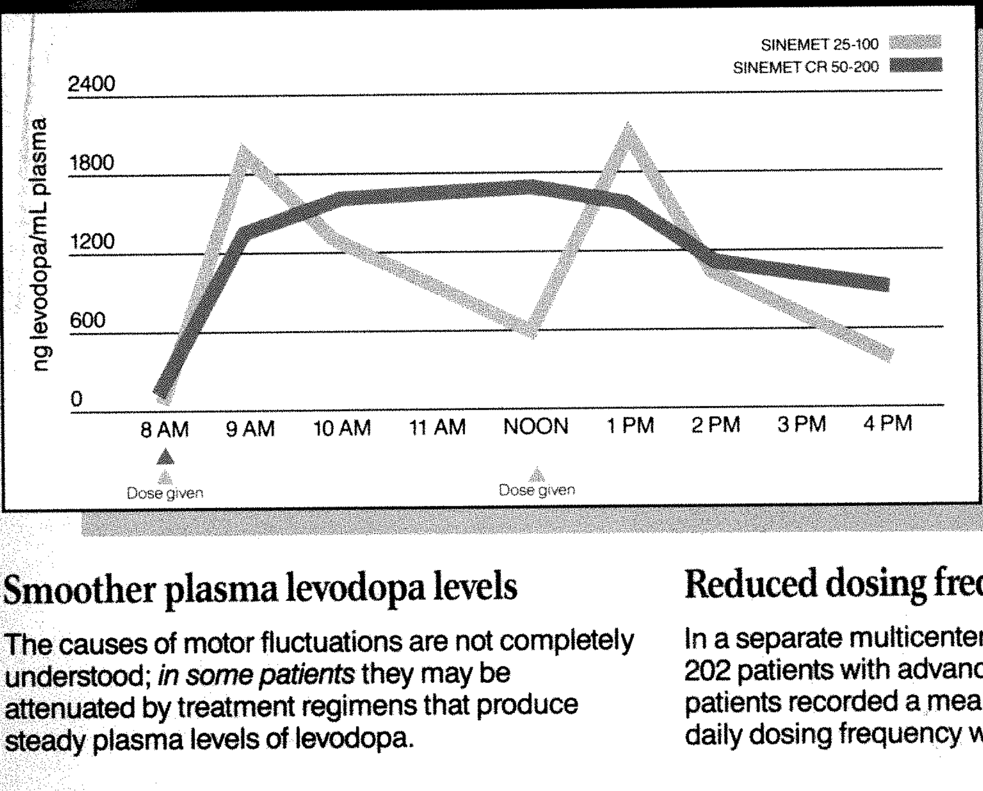
INTRODUCING FROM DU PONT PHARMACEUTICALS
For many patients with Parkinson's disease

SINEMET® CR
(CARBIDOPA-LEVODOPA) SUSTAINED-RELEASE

Smoother Plasma Levodopa Levels*[1]



Less fluctuation of plasma levodopa levels with SINEMET CR vs SINEMET® (Carbidopa-Levodopa)[1]

In a clinical trial, 14 patients with mild to moderate Parkinson's disease had plasma levodopa levels measured over 8 hours after one dose of SINEMET CR, and were compared with levels over the same period after two doses of SINEMET 25-100.

Smoother plasma levodopa levels

The causes of motor fluctuations are not completely understood; *in some patients* they may be attenuated by treatment regimens that produce steady plasma levels of levodopa.

Reduced dosing frequency[2]

In a separate multicenter, double-blind trial of 202 patients with advanced Parkinson's disease, patients recorded a mean reduction of 33% in daily dosing frequency with SINEMET CR.[2]

---

*Patients should be advised that sometimes the onset of effect of the first morning dose of SINEMET CR may be delayed for up to 1 hour compared with the response usually obtained from the first morning dose of SINEMET. The physician should be notified if such delayed responses pose a problem in treatment.

Before prescribing SINEMET CR, please see Full Prescribing Information on the following pages.

® SINEMET is a registered trademark of Merck & Co., Inc., Rahway, NJ, USA

©1991 DuPont Pharmaceuticals Printed in USA CR-31092 8/91

SINEMET CR is indicated in the treatment of the symptoms of idiopathic Parkinson's disease (paralysis agitans), postencephalitic parkinsonism, and symptomatic parkinsonism which may follow injury to the nervous system by carbon monoxide intoxication and manganese intoxication.

1. Goetz CG, Tanner CM, Shannon KM, et al: Controlled-release carbidopa/levodopa (CR4-Sinemet) in Parkinson's disease patients with and without motor fluctuations. *Neurology.* 1988;38:1143-1146.
2. Hutton JT, Morris JL, Bush DF, et al: Multicenter controlled study of Sinemet CR vs Sinemet (25/100) in advanced Parkinson's disease. *Neurology.* 1989;39 (suppl 2): 67-72.

- Significantly greater benefits as rated by patients previously treated with SINEMET® (Carbidopa-Levodopa)‡[2]
- Although in clinical trials, patients with moderate to severe motor fluctuations who received SINEMET® CR (Carbidopa-Levodopa) Sustained-Release *did not experience quantitatively significant reductions* in "off" time when compared to SINEMET, global ratings of improvement as assessed by both patient and physician were better during therapy with SINEMET CR than with SINEMET.
- Significantly greater clinical improvement in patients with moderate to severe motor fluctuations as rated by physicians**[2]
- In controlled clinical trials, patients predominantly with moderate to severe motor fluctuations while on SINEMET were randomized to therapy with either SINEMET or SINEMET CR: *Adverse experience profile of SINEMET CR did not differ substantially from that of SINEMET.*

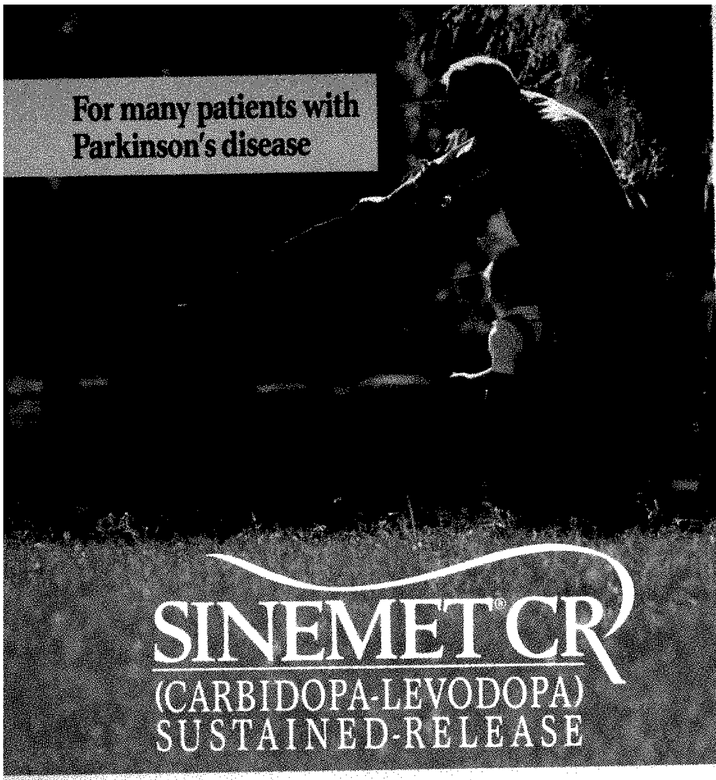
---

†In clinical trials of patients with moderate to severe motor fluctuations, global ratings of improvement as assessed by both patient and physician were better during therapy with SINEMET CR than with SINEMET.

‡Ratings based on patients' subjective assessment of global improvement in clinical fluctuations.

**Physician ratings based on significantly greater overall improvement in patient's clinical condition after eight weeks on SINEMET CR (compared to status at beginning of double-blind phase of same trials).[2]

When patients are receiving levodopa without a decarboxylase inhibitor, levodopa must be discontinued at least eight hours before SINEMET CR is started. It is necessary to individualize therapy. SINEMET CR should be substituted at a dosage that will provide approximately 25% of the previous levodopa dosage. Nonselective MAO inhibitors are contraindicated for use with SINEMET CR. These inhibitors must be discontinued at least two weeks prior to initiating therapy with SINEMET CR. SINEMET CR may be administered concomitantly with the manufacturer's recommended dose of an MAO inhibitor with selectivity for MAO type B, (e.g., selegiline HCl). SINEMET CR is contraindicated in patients with known hypersensitivity to any component of this drug and in patients with narrow-angle glaucoma. Because levodopa may activate a malignant melanoma, SINEMET CR should not be used in patients with suspicious, undiagnosed skin lesions or a history of melanoma.



Guidelines for Initial Conversion from SINEMET® to SINEMET CR

(Carbidopa-Levodopa)

- Dosage with SINEMET CR should be substituted at an amount that provides approximately 10% more levodopa per day. This may be increased to a dosage that provides up to 30% more levodopa per day depending on clinical response. (See DOSAGE AND ADMINISTRATION, *Titration.*)*
- Interval between doses of SINEMET CR should be 4-8 hours during the waking day.
- Doses and dosing intervals may be increased or decreased depending upon therapeutic response.

SINEMET Total daily dose levodopa (mg)	**SINEMET CR** Suggested dosage regimen†
300-400	1 tab b.i.d.
500-600	1½ tab b.i.d. or 1 tab t.i.d.
700-800	A total of 4 tabs in 3 or more divided doses (e.g., 1½ tab a.m., 1½ tab early p.m., and 1 tab later p.m.)
900-1000	A total of 5 tabs in 3 or more divided doses (e.g., 2 tabs a.m., 2 tabs early p.m., and 1 tab later p.m.)

The above is only provided as an example of conversion. Dosage must be individualized and will vary from patient to patient. This example chart reflects dosing of SINEMET CR to provide an increase of approximately 10% more levodopa.

*The bioavailability of levodopa from SINEMET CR relative to SINEMET is approximately 70%-75%.

†For dosing ranges not shown in the table see DOSAGE AND ADMINISTRATION, *Initial Dosage—Patients currently treated with conventional carbidopa-levodopa preparations* of enclosed Full Prescribing Information.

6251-3

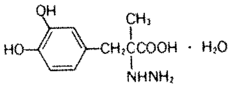
SINEMET® CR (CARBIDOPA-LEVODOPA)

SUSTAINED-RELEASE TABLETS

DESCRIPTION

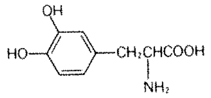
SINEMET* CR (Carbidopa-Levodopa) is a sustained-release combination of carbidopa and levodopa for the treatment of Parkinson's disease and syndrome.

Carbidopa, an inhibitor of aromatic amino acid decarboxylation, is a white, crystalline compound, slightly soluble in water, with a molecular weight of 244.3. It is designated chemically as (−)-L-α-hydrazino-α-methyl-β-(3,4-dihydroxybenzene) propanoic acid monohydrate. Its empirical formula is $C_{10}H_{14}N_2O_4 \bullet H_2O$ and its structural formula is:



Tablet content is expressed in terms of anhydrous carbidopa which has a molecular weight of 226.3.

Levodopa, an aromatic amino acid, is a white, crystalline compound slightly soluble in water, with a molecular weight of 197.2. It is designated chemically as (−)-L-α-amino-β-(3,4-dihydroxybenzene) propanoic acid. Its empirical formula is $C_9H_{11}NO_4$ and its structural formula is:



SINEMET CR is supplied as sustained-release tablets containing 50 mg of carbidopa and 200 mg of levodopa. Inactive ingredients in SINEMET CR are: D & C Yellow 10, magnesium stearate, iron oxide, and other ingredients.

SINEMET CR is supplied as an oval, scored, biconvex, compressed tablet that is peach colored. The tablet is a polymeric-based drug delivery system which controls the release of carbidopa and levodopa as it slowly erodes.

CLINICAL PHARMACOLOGY

Pharmacodynamics Current evidence indicates that symptoms of Parkinson's disease are related to depletion of dopamine in the corpus striatum. Administration of dopamine is ineffective in the treatment of Parkinson's disease apparently because it does not cross the blood-brain barrier. However, levodopa, the metabolic precursor of dopamine, does cross the blood-brain barrier, and presumably is converted to dopamine in the brain. This is thought to be the mechanism whereby levodopa relieves symptoms of Parkinson's disease.

When levodopa is administered orally it is rapidly decarboxylated to dopamine in extracerebral tissues so that only a small portion of a given dose is transported unchanged to the central nervous system. For this reason, large doses of levodopa are required for adequate therapeutic effect and these may often be attended by nausea and other adverse reactions, some of which are attributable to dopamine formed in extracerebral tissues.

Since levodopa competes with certain amino acids for transport across the gut wall, the absorption of levodopa may be impaired in some patients on a high protein diet.

Carbidopa inhibits decarboxylation of peripheral levodopa. It does not cross the blood-brain barrier and does not affect the metabolism of levodopa within the central nervous system.

Since its decarboxylase inhibiting activity is limited to extracerebral tissues, administration of carbidopa with levodopa makes more levodopa available for transport to the brain.

Patients treated with levodopa therapy for Parkinson's disease may develop motor fluctuations characterized by end-of-dose failure, peak dose dyskinesia, and akinesia. The advanced form of motor fluctuations ('on-off' phenomenon) is characterized by unpredictable swings from mobility to immobility. Although the causes of the motor fluctuations are not completely understood, *in some patients* they may be attenuated by treatment regimens that produce steady plasma levels of levodopa.

SINEMET CR contains 50 mg of carbidopa and 200 mg of levodopa in a sustained-release dosage form designed to release these ingredients over a 4 to 6 hour period. With SINEMET CR there is less variation in plasma levodopa levels than with SINEMET* (Carbidopa-Levodopa), the conventional formulation. *However, SINEMET CR (Carbidopa-Levodopa, Sustained-Release) is less systemically bioavailable than SINEMET (Carbidopa-Levodopa) and may require increased daily doses to achieve the same level of symptomatic relief as provided by SINEMET (Carbidopa-Levodopa).*

In clinical trials, patients with moderate to severe motor fluctuations *who received SINEMET CR did not experience quantitatively significant reductions* in 'off' time when compared to SINEMET (Carbidopa-Levodopa). However, global ratings of improvement as assessed by both patient and physician were better during therapy with SINEMET CR than with SINEMET (Carbidopa-Levodopa). In patients without motor fluctuations, SINEMET CR, under controlled conditions, provided the same therapeutic benefit with less frequent dosing when compared to SINEMET (Carbidopa-Levodopa).

Pyridoxine hydrochloride (vitamin B_6), in oral doses of 10 mg to 25 mg, may reverse the effects of levodopa by increasing the rate of aromatic amino acid decarboxylation. Carbidopa inhibits this action of pyridoxine.

Pharmacokinetics Carbidopa reduces the amount of levodopa required to produce a given response by about 75 percent and, when administered with levodopa, increases both plasma levels and the plasma half-life of levodopa, and decreases plasma and urinary dopamine and homovanillic acid.

Elimination half-life of levodopa in the presence of carbidopa is about 1.5 hours. Following SINEMET CR, the apparent half-life of levodopa may be prolonged because of continuous absorption.

In healthy elderly subjects (56-67 years old) the mean time to peak concentration of levodopa after a single dose of SINEMET CR 50-200 was about 2 hours as compared to 0.5 hours after standard SINEMET (Carbidopa-Levodopa). The maximum concentration of levodopa after a single dose of SINEMET CR was about 35% of the standard SINEMET (Carbidopa-Levodopa) (1151 vs 3256 ng/mL). The extent of availability of levodopa from SINEMET CR was about 70-75% relative to intravenous levodopa or standard SINEMET (Carbidopa-Levodopa) in the elderly. The absolute bioavailability of levodopa from SINEMET CR (relative to I.V.) in young subjects was shown to be only about 44%. The extent of availability and the peak concentrations of levodopa were comparable in the elderly after a single dose and at steady state after t.i.d. administration of SINEMET CR 50-200. In elderly subjects, the average trough levels of levodopa at steady state after the CR tablet were about 2 fold higher than after the standard SINEMET (Carbidopa-Levodopa) (163 vs 74 ng/mL).

In these studies, using similar total daily doses of levodopa, plasma levodopa concentrations with SINEMET CR fluctuated in a narrower range than with SINEMET (Carbidopa-Levodopa). Because the bioavailability of levodopa from SINEMET CR relative to SINEMET (Carbidopa-Levodopa) is approximately 70-75% the daily dosage of levodopa necessary to produce a given clinical response with the sustained-release formulation will usually be higher.

The extent of availability and peak concentrations of levodopa after a single dose of SINEMET CR 50-200, increased by about 50% and 25%, respectively, when administered with food.

INDICATIONS AND USAGE

SINEMET CR is indicated in the treatment of the symptoms of idiopathic Parkinson's disease (paralysis agitans), postencephalitic parkinsonism, and symptomatic parkinsonism which may follow injury to the nervous system by carbon monoxide intoxication and manganese intoxication.

CONTRAINDICATIONS

Nonselective MAO inhibitors are contraindicated for use with SINEMET CR. These inhibitors must be discontinued at least two weeks prior to initiating therapy with SINEMET CR. SINEMET CR may be administered concomitantly with the manufacturer's recommended dose of an MAO inhibitor with selectivity for MAO type B (e.g., selegiline HCl).

SINEMET CR is contraindicated in patients with known hypersensitivity to any component of this drug and in patients with narrow-angle glaucoma.

Because levodopa may activate a malignant melanoma, SINEMET CR should not be used in patients with suspicious, undiagnosed skin lesions or a history of melanoma.

WARNINGS

When patients are receiving levodopa without a decarboxylase inhibitor, levodopa must be discontinued at least eight hours before SINEMET CR is started. In order to reduce adverse reactions, it is necessary to individualize therapy. SINEMET CR should be substituted at a dosage that will provide approximately 25 percent of the previous levodopa dosage (see DOSAGE AND ADMINISTRATION).

Carbidopa does not decrease adverse reactions due to central effects of levodopa. By permitting more levodopa to reach the brain, particularly when nausea and vomiting is not a dose-limiting factor, certain adverse CNS effects, e.g., dyskinesias, will occur at lower dosages and sooner during therapy with SINEMET CR (Carbidopa-Levodopa, Sustained-Release) than with levodopa alone.

As with levodopa, SINEMET CR may cause involuntary movements and mental disturbances. These reactions are thought to be due to increased brain dopamine following administration of levodopa. All patients should be observed carefully for the development of depression with concomitant suicidal tendencies. Patients with past or current psychoses should be treated with caution. The occurrence of dyskinesias may require dosage reduction.

Patients receiving SINEMET CR may develop increased dyskinesia compared to SINEMET (Carbidopa-Levodopa).

SINEMET CR should be administered cautiously to patients with severe cardiovascular or pulmonary disease, bronchial asthma, renal, hepatic or endocrine disease.

As with levodopa, care should be exercised in administering SINEMET CR to patients with a history of myocardial infarction who have residual atrial, nodal, or ventricular arrhythmias. In such patients, cardiac function should be monitored with particular care during the period of initial dosage adjustment, in a facility with provisions for intensive cardiac care.

As with levodopa, treatment with SINEMET CR may increase the possibility of upper gastrointestinal hemorrhage in patients with a history of peptic ulcer.

A symptom complex resembling the neuroleptic malignant syndrome including muscular rigidity, elevated body temperature, mental changes, and increased serum creatine phosphokinase has been reported when antiparkinsonian agents were withdrawn abruptly. Therefore, patients should be observed carefully when the dosage of SINEMET CR is reduced abruptly or discontinued, especially if the patient is receiving neuroleptics.

PRECAUTIONS

General As with levodopa, periodic evaluations of hepatic, hematopoietic, cardiovascular, and renal function are recommended during extended therapy.

Patients with chronic wide angle glaucoma may be treated cautiously with SINEMET CR provided the intraocular, pressure is well controlled and the patient is monitored carefully for changes in intraocular pressure during therapy.

Information for Patients The patient should be informed that SINEMET CR is a sustained-release formulation of carbidopa-levodopa which releases these ingredients over a 4 to 6 hour period. It is important that SINEMET CR be taken at regular intervals according to the schedule outlined by the physician. The patient should be cautioned not to change the prescribed dosage regimen and not to add any additional antiparkinson medications, including other carbidopa-levodopa preparations, without first consulting the physician.

If abnormal involuntary movements appear or get worse during treatment with SINEMET CR, the physician should be notified, as dosage adjustment may be necessary.

Patients should be advised that sometimes the onset of effect of the first morning dose of SINEMET CR may be delayed for up to 1 hour compared with the response usually obtained from the first morning dose of SINEMET (Carbidopa-Levodopa). The physician should be notified if such delayed responses pose a problem in treatment.

Patients must be advised that the whole or half tablet should be swallowed without chewing or crushing.

NOTE: The suggested advice to patients being treated with SINEMET CR is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Laboratory Tests Abnormalities in laboratory tests may include elevations of liver function tests such as alkaline phosphatase, SGOT (AST), SGPT (ALT), lactic dehydrogenase, and bilirubin. Abnormalities in blood urea nitrogen and positive Coombs test have also been reported. Commonly, levels of blood urea nitrogen, creatinine, and uric acid are lower during administration of carbidopa-levodopa preparations than with levodopa.

Carbidopa-levodopa preparations may cause a false-positive reaction for urinary ketone bodies when a test tape is used for determination of ketonuria. This reaction will not be altered by boiling the urine specimen. False-negative tests may result with the use of glucose-oxidase methods of testing for glucosuria.

Drug Interactions *Caution should be exercised when the following drugs are administered concomitantly with SINEMET CR (Carbidopa-Levodopa, Sustained-Release).*

Symptomatic postural hypotension has occurred when carbidopa-levodopa preparations were added to the treatment of patients receiving some antihypertensive drugs. Therefore, when therapy with SINEMET CR is started, dosage adjustment of the antihypertensive drug may be required. For patients receiving monoamine oxidase inhibitors, see CONTRAINDICATIONS.

There have been rare reports of adverse reactions, including hypertension and dyskinesia, resulting from the concomitant use of tricyclic antidepressants and carbidopa-levodopa preparations.

Phenothiazines and butyrophenones may reduce the therapeutic effects of levodopa. In addition, the beneficial effects of levodopa in Parkinson's disease have been reported to be reversed by phenytoin and papaverine. Patients taking these drugs with SINEMET CR should be carefully observed for loss of therapeutic response.

Carcinogenesis, Mutagenesis, Impairment of Fertility In a two-year bioassay of SINEMET (Carbidopa-Levodopa), no evidence of carcinogenicity was found in rats receiving doses of approximately two times the maximum daily human dose of carbidopa and four times the maximum daily human dose of levodopa (equivalent to 8 SINEMET CR tablets).

In reproduction studies with SINEMET (Carbidopa-Levodopa), no effects on fertility were found in rats receiving doses of approximately two times the maximum daily human dose of carbidopa and four times the maximum daily human dose of levodopa (equivalent to 8 SINEMET CR tablets).

Pregnancy Pregnancy Category C. No teratogenic effects were observed in a study in mice receiving up to 20 times the maximum recommended human dose of SINEMET (Carbidopa-Levodopa). There was a decrease in the number of live pups delivered by rats receiving approximately two times the maximum recommended human dose of carbidopa and approximately five times the maximum recommended human dose of levodopa during organogenesis. SINEMET (Carbidopa-Levodopa) caused both visceral and skeletal malformations in rabbits at all doses and ratios of carbidopa/levodopa tested, which ranged from 10 times/5 times the maximum recommended human dose of carbidopa/levodopa to 20 times/10 times the maximum recommended human dose of carbidopa/levodopa.

There are no adequate or well-controlled studies in pregnant women. Use of SINEMET CR in women of childbearing potential requires that the anticipated benefits of the drug be weighed against possible hazards to mother and child.

Nursing Mothers It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when SINEMET CR is administered to a nursing mother.

Pediatric Use Safety and effectiveness in infants and children have not been established, and use of the drug in patients below the age of 18 is not recommended.

ADVERSE REACTIONS

In controlled clinical trials, patients predominantly with moderate to severe motor fluctuations, while on SINEMET (Carbidopa-Levodopa) were randomized to therapy with either SINEMET (Carbidopa-Levodopa) or SINEMET CR. The adverse experience frequency profile of SINEMET CR did not differ substantially from that of SINEMET (Carbidopa-Levodopa), as shown in Table 1.

Table 1 Clinical Adverse Experiences Occurring in 1% or Greater of Patients

Adverse Experience	**SINEMET CR** n=491 %	**SINEMET** (Carbidopa-Levodopa) n=524 %	Adverse Experience	**SINEMET CR** n=491 %	**SINEMET** (Carbidopa-Levodopa) n=524 %
Dyskinesia	16.5	12.2	Back Pain	1.6	0.6
Nausea	5.5	5.7	Dry Mouth	1.4	1.1
Hallucinations	3.9	3.2	Anorexia	1.2	1.1
Confusion	3.7	2.3	Diarrhea	1.2	0.6
Dizziness	2.9	2.3	Insomnia	1.2	1.0
Depression	2.2	1.3	Orthostatic Hypotension	1.0	1.1
Urinary Tract Infection	2.2	2.3	Shoulder Pain	1.0	0.6
Headache	2.0	1.9	Chest Pain	1.0	0.8
Dream Abnormalities	1.8	0.8	Muscle Cramps	0.8	1.0
Dystonia	1.8	0.8	Paresthesia	0.8	1.1
Vomiting	1.8	1.9	Urinary Frequency	0.8	1.1
Upper Respiratory Infection	1.8	1.0	Dyspepsia	0.6	1.1
Dyspnea	1.6	0.4	Constipation	0.2	1.5
'On-Off' Phenomena	1.6	1.1			

Abnormal laboratory findings occurring at a frequency of 1% or greater in approximately 443 patients who received SINEMET CR and 475 who received SINEMET (Carbidopa-Levodopa) during controlled clinical trials included: decreased hemoglobin and hematocrit; elevated serum glucose; white blood cells, bacteria and blood in the urine.

The adverse experiences observed in patients in uncontrolled studies were similar to those seen in controlled clinical studies.

Other adverse experiences reported overall in clinical trials in 748 patients treated with SINEMET CR, listed by body system in order of decreasing frequency, include:

Nervous System/Psychiatric: Chorea, somnolence, falling, anxiety disorder, disorientation, decreased mental acuity, gait abnormalities, extrapyramidal disorder, agitation, nervousness, sleep disorders, memory impairment.
Body as a Whole: Asthenia, fatigue, abdominal pain, orthostatic effects.
Digestive: Gastrointestinal pain, dysphagia, heartburn.
Cardiovascular: Palpitation, essential hypertension, hypotension, myocardial infarction.
Special Senses: Blurred vision.
Metabolic: Weight loss.
Skin: Rash.
Respiratory: Cough, pharyngeal pain, common cold.
Urogenital: Urinary incontinence.
Musculoskeletal: Leg pain.
Laboratory Tests: Decreased white blood cell count and serum potassium; increased BUN, serum creatinine and serum LDH; protein and glucose in the urine.

Other adverse experiences have been reported with various cabidopa-levodopa formulations and may occur with SINEMET CR:

Nervous System/Psychiatric: Mental changes including paranoid ideation, psychotic episodes, depression with suicidal tendencies and dementia; convulsions (however, a causal relationship has not been established); bradykinetic episodes.
Gastrointestinal: Gastrointestinal bleeding, development of duodenal ulcer.
Cardiovascular: Cardiac irregularities, phlebitis.
Hematologic: Hemolytic and nonhemolytic anemia, thrombocytopenia, leukopenia, agranulocytosis.
Laboratory Tests: Abnormalities in alkaline phosphatase, SGOT (AST), SGPT (ALT), lactic dehydrogenase, bilirubin, protein-bound iodine, Coombs test.

7619403
6251-3

Other adverse reactions that have been reported with levodopa are:

Nervous System: Numbness, increased hand tremor, muscle twitching, blepharospasm (which may be taken as an early sign of excess dosage, consideration of dosage reduction may be made at this time), trismus, activation of latent Horner's syndrome.
Psychiatric: Delusions, euphoria.
Gastrointestinal: Bitter taste, sialorrhea, bruxism, hiccups, flatulence, burning sensation of tongue.
Metabolic: Weight gain, edema.
Integumentary: Malignant melanoma (see also CONTRAINDICATIONS), flushing, increased sweating, dark sweat, loss of hair.
Genitourinary: Urinary retention, urinary incontinence, dark urine, priapism.
Miscellaneous: Faintness, hoarseness, malaise, hot flashes, sense of stimulation, bizarre breathing patterns, neuroleptic malignant syndrome.

OVERDOSAGE

Management of acute overdosage with SINEMET CR is the same as with levodopa. Pyridoxine is not effective in reversing the actions of SINEMET CR.

General supportive measures should be employed, along with immediate gastric lavage. Intravenous fluids should be administered judiciously and an adequate airway maintained. Electrocardiographic monitoring should be instituted and the patient carefully observed for the development of arrhythmias; if required, appropriate antiarrhythmic therapy should be given. The possibility that the patient may have taken other drugs as well as SINEMET CR should be taken into consideration. To date, no experience has been reported with dialysis; hence, its value in overdosage is not known.

Based on studies in which high doses of levodopa and/or carbidopa were administered, a significant proportion of rats and mice given single oral doses of levodopa of approximately 1500-2000 mg/kg are expected to die. A significant proportion of infant rats of both sexes are expected to die at a dose of 800 mg/kg. A significant proportion of rats are expected to die after treatment with similar doses of carbidopa. The addition of carbidopa in a 1:10 ratio with levodopa increases the dose at which a significant proportion of mice are expected to die to 3360 mg/kg.

DOSAGE AND ADMINISTRATION

SINEMET CR tablets contain carbidopa (50 mg) and levodopa (200 mg) in a 1:4 ratio. The daily dosage of SINEMET CR must be determined by careful titration. Patients should be monitored closely during the dose adjustment period, particularly with regard to appearance or worsening of involuntary movements, dyskinesias or nausea. SINEMET CR may be administered as whole or as half-tablets which should not be chewed or crushed.

Standard drugs for Parkinson's disease, other than levodopa without a decarboxylase inhibitor, may be used concomitantly while SINEMET CR is being administered, although their dosage may have to be adjusted.

Since carbidopa prevents the reversal of levodopa effects caused by pyridoxine, SINEMET CR can be given to patients receiving supplemental pyridoxine (vitamin B_6).

Initial Dosage *Patients currently treated with conventional carbidopa-levodopa preparations:* Dosage with SINEMET CR should be substituted at an amount that provides approximately 10% more levodopa per day, although this may need to be increased to a dosage that provides up to 30% more levodopa per day depending on clinical response (see DOSAGE AND ADMINISTRATION, TITRATION). The interval between doses of SINEMET CR should be 4-8 hours during the waking day. (See CLINICAL PHARMACOLOGY, *Pharmacodynamics*).

A guideline for *initiation* of SINEMET CR is shown in Table II.

TABLE II Guidelines for Initial Conversion from SINEMET (Carbidopa-Levodopa) to SINEMET CR	**SINEMET (Carbidopa-Levodopa)** Total Daily Dose* Levodopa (mg)	**SINEMET CR** Suggested Dosage Regimen
	300-400	1 tab b.i.d.
	500-600	1½ tab b.i.d. or 1 tab t.i.d.
	700-800	A total of 4 tabs in 3 or more divided doses (e.g., 1½ tab a.m., 1½ tab early p.m., and 1 tab later p.m.)
	900-1000	A total of 5 tabs in 3 or more divided doses (e.g., 2 tabs a.m., 2 tabs early p.m., and 1 tab later p.m.)

*For dosing ranges not shown in the table see DOSAGE AND ADMINISTRATION, *Initial Dosage—Patients currently treated with conventional carbidopa-levodopa preparations.*

Patients currently treated with levodopa without a decarboxylase inhibitor: Levodopa must be discontinued at least eight hours before therapy with SINEMET CR is started. SINEMET CR should be substituted at a dosage that will provide approximately 25% of the previous levodopa dosage. In patients with mild to moderate disease, the initial dose is usually 1 tablet of SINEMET CR b.i.d.

Patients not receiving levodopa: In patients with mild to moderate disease, the initial recommended dose is 1 tablet of SINEMET CR b.i.d. Initial dosage should not be given at intervals of less than 6 hours.

Titration Following initiation of therapy, doses and dosing intervals may be increased or decreased depending upon therapeutic response. Most patients have been adequately treated with 2 to 8 tablets per day, administered as divided doses at intervals ranging from 4 to 8 hours during the waking day. Higher doses (12 or more tablets per day) and shorter intervals (less than 4 hours) have been used, but are not usually recommended.

When doses of SINEMET CR are given at intervals of less than 4 hours, and/or if the divided doses are not equal, it is recommended that the smaller doses be given at the end of the day.

An interval of at least 3 days between dosage adjustments is recommended.

Maintenance Because Parkinson's disease is progressive, periodic clinical evaluations are recommended; adjustment of the dosage regimen of SINEMET CR may be required.

Addition of Other Antiparkinson Medications Anticholinergic agents, dopamine agonists, and amantadine can be given with SINEMET CR. Dosage adjustment of SINEMET CR may be necessary when these agents are added.

A dose of SINEMET (Carbidopa-Levodopa) 25-100 or 10-100 (one half or a whole tablet) can be added to the dosage regimen of SINEMET CR in selected patients with advanced disease who need additional levodopa for a brief time during daytime hours.

Interruption of Therapy Patients should be observed carefully if abrupt reduction or discontinuation of SINEMET CR is required, especially if the patient is receiving neuroleptics. (See WARNINGS).

If general anesthesia is required, SINEMET CR may be continued as long as the patient is permitted to take oral medication. If therapy is interrupted temporarily, the usual dosage should be administered as soon as the patient is able to take oral medication.

HOW SUPPLIED

SINEMET CR 50-200 (Carbidopa-Levodopa) SUSTAINED-RELEASE TABLETS containing 50 mg of carbidopa and 200 mg of levodopa, are peach-colored, oval, scored, biconvex, compressed tablets, coded 521. They are supplied as follows:

NDC 0056-0521-68 bottles of 100
NDC 0056-0521-28 unit dose packages of 100.

Storage Avoid temperatures above 30°C (86°F). Store in a tightly closed container.

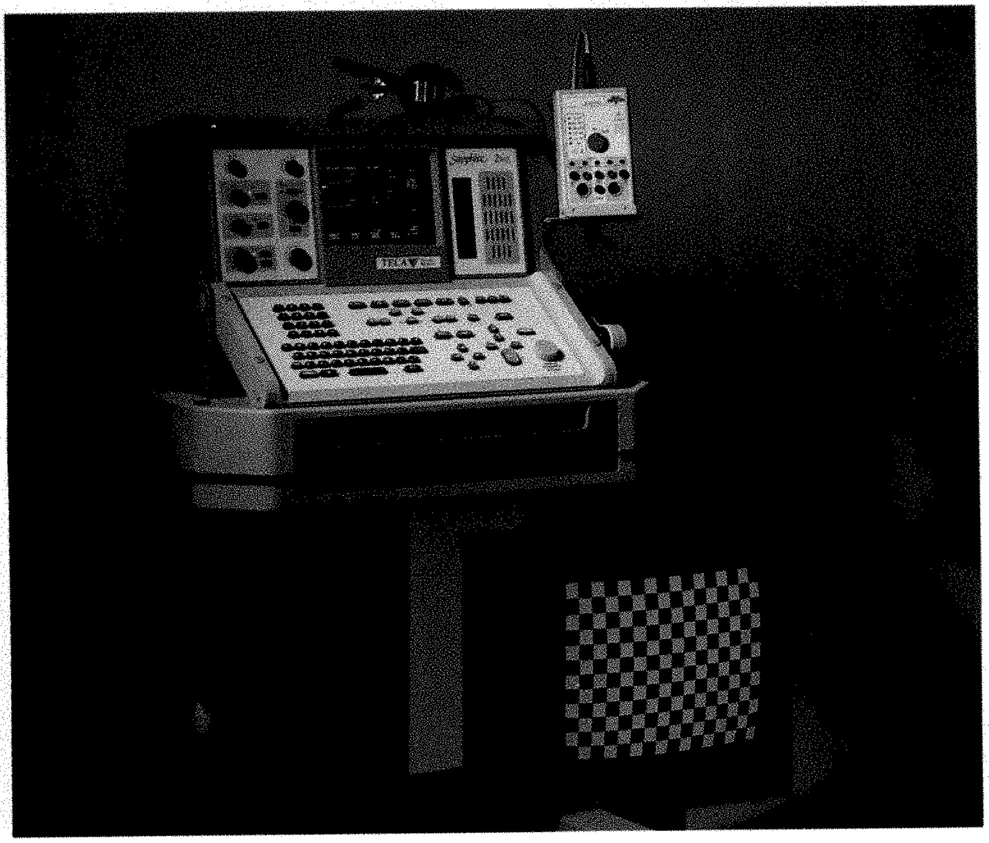
EMG/EP FOR THE 90'S FROM TECA



In the 90's two seemingly disparate terms – **advanced technology and affordability–** were linked when TECA announced the Sapphire line of portable EMG/EP instruments. Sapphire delivers all the advantages of modern technology with pricing that is realistic in today's economic environment.

- Superfast real-time EMG
- 1 or 2 channels
- EP stims
- Automatic NCV studies
- 10 seconds of EMG memory
- Trigger and delay line
- 16 programmable tests
- High resolution 12 bit A/D
- Trace annotation
- Disk drive and reporting
- Fast thermal printout

The Sapphire range is available from a single channel EMG instrument, to a full function EMG with Evoked Potentials. All routine tests are performed at the push of a button.

TECA Corporation, in the forefront with innovative instrumentation and a reputation for quality and service for over 40 years.

Series Editors: F. Boller & J. Grafman **ISBN Series: 0-444-90492-1**

HANDBOOK OF NEUROPSYCHOLOGY

Research and clinical studies in recent years have shown an enormous increase in interest into disorders of higher cortical functions and brain-behavior relationships. **The Handbook of Neuropsychology** meets this growing interest by providing for the first time, a comprehensive and current examination of ***both*** experimental ***and*** clinical aspects of neuropsychology. Subjects covered include Attention, Language, Aphasia and Related Disorders, Visual Behavior, Memory, The Commissurotomized Brain, Aging and Dementia and Child Neuropsychology.

Volume 1
Section Editors: F. Boller, J. Grafman, G. Rizzolatti & H. Goodglass

The first volume serves as an Introduction to the Series and features coverage of Attention, as well as Language and Aphasia.

1988 : xv + 441 pages
Hardback: ISBN 0-444-90493-X / US$ 197.25/Dfl. 345.00
Paperback: ISBN 0-444-81215-6 / US$ 68.75/Dfl. 120.00

Volume 2
Section Editors: H. Goodglass & A.R. Damasio

Continues the subject of language and aphasia (from Vol. 1), and covers disorders of visual behavior.

1989 : xv + 436 pages
Hardback: ISBN 0-444-81062-5 / US$ 217.25/Dfl. 380.00
Paperback: ISBN 0-444-81310-1 / US$ 65.75/Dfl. 115.00

Volume 3
Section Editors: L. Squire & G. Gainotti

One section deals with memory and its disorders. Specific topics include the organization and neurological foundations of memory, the neuropsychological foundations of memory, and the neuropsychological assessment of learning and memory. A second section covers emotional behavior and its disorders, and includes a review of theories of emotion, the anatomical and neurochemical bases of emotional behavior, as well as specific disorders of emotion and emotional arousal including anxiety and depression.

1989 : xiv + 501 pages
Hardback: ISBN 0-444-81090-0 / US$ 245.75/Dfl. 430.00
Paperback: ISBN 0-444-89168-4 / US$80.00/Dfl.140.00

Volume 4
Section Editors: R.D. Nebes & S. Corkin

One section includes chapters on the commissurotomized brain and the other section deals with aging, age-related disorders and dementia and covers the neuropsychology of aging in animals and humans; clinical and pathological correlates of dementia; as well as modern clinical and experimental techniques such as PET and NMR spectroscopy.

1990 : xiv + 383 pages
Hardback: ISBN 0-444-81234-2 / US$ 205.75/Dfl. 360.00
Paperback: ISBN 0-444-89169-2 / US$ 72.50/Dfl. 127.00

NEW:
Volume 5
Section Editors: S. Corkin, J. Grafman & F. Boller

This volume continues the aging and dementia section (from Vol. 4), and contains a section on cognitive, methodological and practical approaches to neuropsychology.

To be published May 1991
Hardback: ISBN 0-444-81233-4 / US$211.50/Dfl. 370.00

FORTHCOMING:
***Volumes 6 & 7:* Child Neuropsychology**
Section Editors: I. Rapin & S.J. Segalowitz
These volumes will be published in late 1991/early 1992

Full contents lists of all volumes available from the publishers on request

> *"a very useful series which is likely to be a welcome addition to many libraries ... brings together a wealth of material from the rapidly expanding field of neuropsychology in a generally competent and authoritative manner"*

"As doctors, if we do the right thing at the right time, we can make a difference."

Dr. Kenneth A. Haller, Pediatrician, East St. Louis, Illinois, Member, American Medical Association

In one of the nation's poorest communities, Dr. Kenneth Haller is working not only to save children's lives, but to bring dignity to the lives of their parents.

He is the type of physician who brings distinction to our profession. He is the type of physician who upholds the highest ideals of medicine. He is also a member of the American Medical Association (AMA).

"I read the Principles of Medical Ethics of the AMA and was impressed by it. I'm proud to be a member," says Dr. Haller.

You are invited to join Dr. Haller and to join with him in his efforts to bring quality health care to those in need. To become a member of the AMA, return the attached postage-paid card or call our toll-free number now. 1-800-AMA-3211.

Physicians dedicated to the health of America

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, Robert J. Joynt, MD, PhD, University of Rochester School of Medicine and Dentistry, 601 Elmwood Ave, Rochester, NY 14642. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the Archives and may not be published elsewhere without permission from the publisher (AMA).

Cover Letter.—Designate one author as correspondent and provide a complete address and telephone number.

In the cover letter include (1) statement on authorship responsibility, (2) statement on financial disclosure, and (3) one of the two following statements on copyright *or* federal employment. Each of these three statements must be signed by *all* authors.

1. Authorship Responsibility.—"I certify that I have participated sufficiently in the conception and design of this work and the analysis of the data (when applicable), as well as the writing of this manuscript, to take public responsibility for it. I believe the manuscript represents valid work. I have reviewed the final version of the manuscript and approve it for publication. Neither this manuscript nor one with substantially similar content under my authorship has been published or is being considered for publication elsewhere, except as described in an attachment. Furthermore, I attest that I shall produce the data upon which the manuscript is based for examination by the editors or their assignees if requested."

2. Financial Disclosure.—"I certify that affiliations (if any) with or involvement in any organization or entity with a direct financial interest in the subject matter or materials discussed in the manuscript (eg, employment, consultancies, stock ownership, honoraria, expert testimony) are disclosed below."

Research or project support should be listed in an acknowledgement.

3a. Copyright Transfer.—"In consideration of the action of the American Medical Association (AMA) in reviewing and editing this submission, the author(s) undersigned hereby transfer(s) assign(s), or otherwise convey(s) all copyright ownership to the AMA in the event that such work is published by the AMA."

3b. Federal Employment.—"I was an employee of the US federal government when this work was investigated and prepared for publication; therefore, it is not protected by the Copyright Act and there is no copyright of which the ownership can be transferred."

We regret that transmittal letters not containing the preceding language signed by all authors of the submission will necessitate delay in review of the manuscript.

Editing.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit three high-quality copies of the entire manuscript. The copies will not be returned. The authors should keep the original manuscript for submission if accepted. The original manuscript (including references, legends, and tables) must be typed double-spaced on 21.6 × 27.9-cm 8½ × 11-in), heavy-duty white bond paper. Ample margins of at least 2.5 cm (1 in) should be provided. **If a word processor is used, do not justify right-hand margins.**

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, and the address to which requests for reprints should be sent.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of the article, including statements of the problem, method of study, results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (not alphabetically). Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communications should not be listed as references. References to journal articles should include (1) author(s) (list all authors and/or editors up to six; if more than six, list the first three and "et al"), (2) title, (3) journal name (as abbreviated in *Index Medicus*), (4) year, (5) volume number, and (6) inclusive page numbers, in that order. References to books should include (1) author(s) (list all authors and/or editors up to six; if more than six, list the first three and "et al"), (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) city of publication, (6) publisher, and (7) year. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. **The author is responsible for the accuracy and completeness of the references and for their correct text citation.**

SI Units.—Use Système International (SI) measurements throughout the manuscript. (See June 1986 issue of the Archives.)

Illustrations.—The illustrations originally submitted will not be returned. High-quality copies may be used. Original illustrations should be kept by the author for submission if the manuscript is accepted. Use only those illustrations that clarify and augment the text. If accepted, submit illustrations in triplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Magnification and stain should be provided when pertinent. Illustrations should preferably be in a proportion of 12.7 × 7.3 cm (5 × 7 in).

Template lettering or preset type is preferred to hand-lettered labels. If halftone artwork with labels is submitted, affix type and leaders to a clear acetate overlay registered to the base drawing. Labels and leaders should be applied directly to the drawing board surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if the editors believe that color will add significantly to the published manuscript. The Archives will pay part of the expense of reproduction and printing color illustrations, the remainder to be borne by the author or his sponsor. After deducting the Archives' contribution, the author's share is $400 for up to six square-finished illustrations that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35 mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies. All transparencies should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning on a separate sheet of paper. Length should be limited to a maximum of 40 words.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: author(s), title of article, title of journal or book, volume number, page(s), month, and year. The publisher's permission to reprint should be submitted to the Archives after the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluations should include the name and affiliation of the statistical reviewer.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 21.6 × 27.9-cm (8½ × 11-in) paper. Do not use larger size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

MULTIPLE SCLEROSIS RESEARCH PROJECTS

Available Online Exclusively on the *Life Science Network*℠.

Now you have the opportunity to keep track of research in progress on multiple sclerosis through the ***Multiple Sclerosis Research Projects*** database!

Brought to you by BIOSIS, the world's largest life science database producer and publisher of ***Biological Abstracts***®, and the International Federation of Multiple Sclerosis Societies, ***Multiple Sclerosis Research Projects*** is the definitive, single source for information of this kind.

Multiple Sclerosis Research Projects helps you access summary information on basic research currently under way on multiple sclerosis, including clinical, rehabilitative, social studies, and other fields. ***Multiple Sclerosis Research Projects*** references also list the source and length of the research grant, as well as the name and address of the researcher — a real plus when you need to communicate directly with your colleagues!

For more information on ***Multiple Sclerosis Research Projects*** and the ***Life Science Network***, contact the BIOSIS Marketing Department AN991MS, 2100 Arch Street, Philadelphia, PA 19103-1399 USA. Or call toll free 1-800-523-4806 (USA except PA); (215) 587-4800 (worldwide); Fax (215) 587-2016.

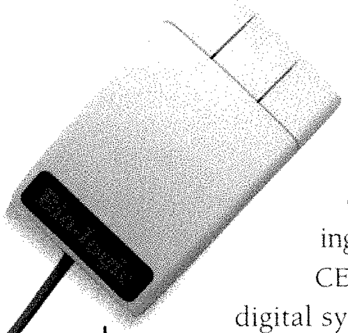
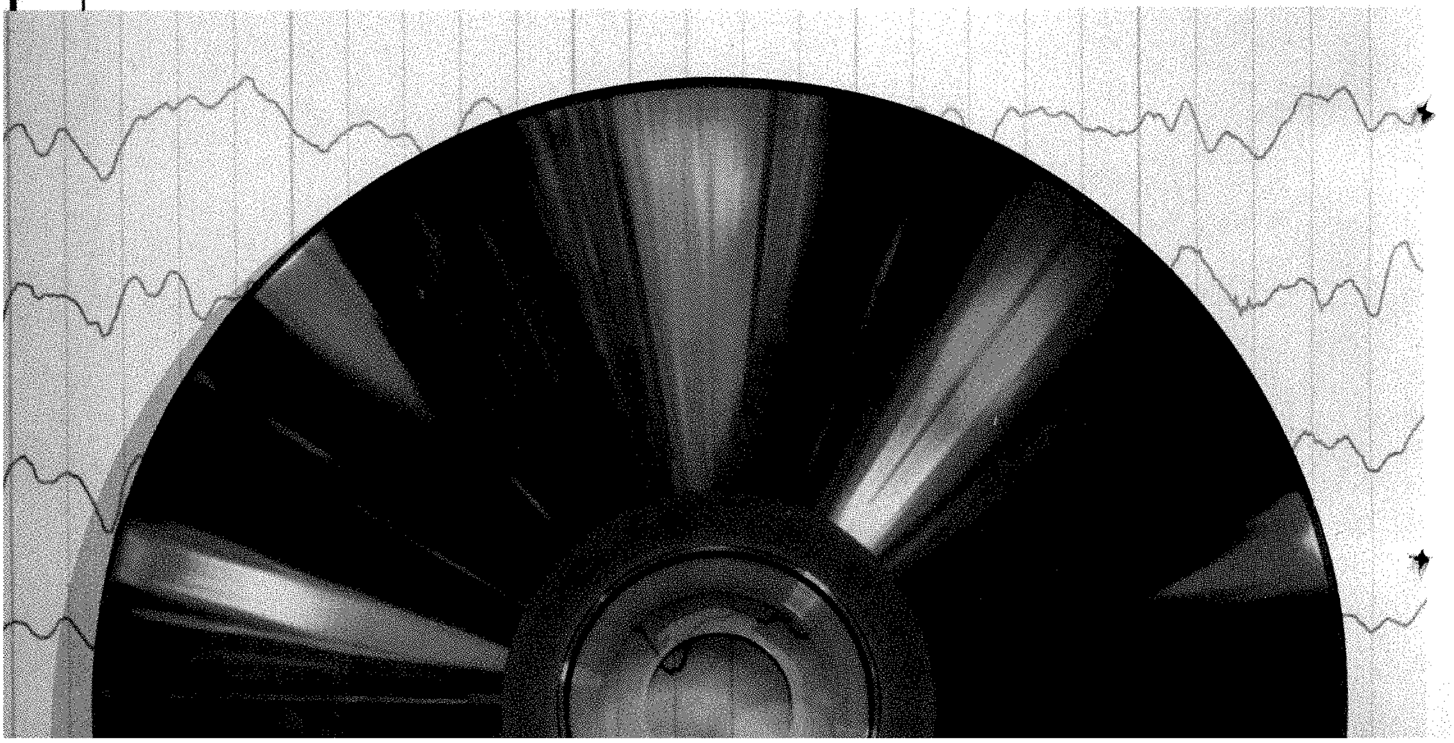
Now you can see more than ever before. CEEGRAPH™ Digital EEG.

Advanced capabilities. Enhanced analysis. All without changing your procedures. That's where evolution has led EEG—to improved technology that helps your lab realize its full diagnostic testing potential. Introducing CEEGRAPH, the evolution of EEG. CEEGRAPH is the high-resolution, digital system that offers everything you expect from traditional EEG, and more. Now you can remontage previously acquired EEG tracings

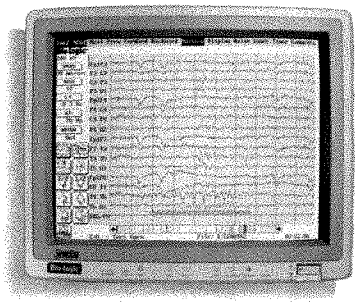
JOIN THE E





to localize events that occurred during testing. Change paper speeds after the fact to enhance characteristics of the tracing. Immediately access any area of interest. Plus, easily obtain your patient's brief history.

CEEGRAPH. Join the evolution and bring your lab into a new world of possibilities.



VOLUTION

Changing the way you look at EEG doesn't mean changing the way EEG looks.

Evolution in technology doesn't mean a revolution in the way you work. CEEGRAPH brings you advanced capabilities, without changing your procedures. A simple click or a keystroke puts you in control and lets you see everything you want to see.

And CEEGRAPH reduces your operating budget with cost-effective EEG storage. Optical disks, removable hard disk cartridges or videocassettes store data to minimize paper and ink usage.

Invest in the future.

Don't get left behind. If you're looking to replace or add an EEG system, you owe it to your lab to see a demonstration of CEEGRAPH. From individual components that work with your existing EEG instrument to a complete digital system, CEEGRAPH grows with your lab to enhance your capabilities. And CEEGRAPH offers you the opportunity to totally integrate your entire electrodiagnostic laboratory, from EP and EMG to brain mapping and polysomnography.

Start the evolution in your lab today—get the facts on CEEGRAPH. Call 1-800-323-8326* and we'll immediately FAX you a report of CEEGRAPH'S unique features and benefits.

Get the FAX.

And One For Treating It.

Topical
Zostrix®
(Capsaicin 0.025% w/w) Cream

When patients describe the "hurt" of postherpetic neuralgia (PHN), they use a wide range of words to describe a pain that is often intractable and difficult to treat. Zostrix® (Capsaicin 0.025% w/w) Cream provides an effective topical treatment that alleviates intense pain in most PHN patients.

Topical Zostrix Works Where It Hurts

Zostrix®

(Capsaicin 0.025% w/w) Cream

Topical Analgesic

TARGETED ACTION
Acts on sensory nerves at site of application by selectively depleting substance P, a chemomediator of pain impulses along neuropathways.

EFFECTIVE
Alleviates the intense pain associated with postherpetic neuralgia in most patients. May also benefit patients when added to existing systemic drug regimens.

SAFE
No known interactions with systemic medications commonly prescribed for geriatric patients.

Topical Zostrix Works Where It Hurts

DESCRIPTION

Zostrix Cream contains capsaicin, 0.025% w/w, in an emollient base containing benzyl alcohol, cetyl alcohol, glyceryl monostearate, isopropyl myristate, polyoxyethylene stearate blend, purified water, sorbitol solution and white petrolatum. Capsaicin is a naturally occurring substance derived from plants of the Solanaceae family with the chemical name trans-8-methyl-N-vanillyl-6-nonenamide. Capsaicin is a white crystalline powder with a molecular weight of 305.4. It is practically insoluble in water but very soluble in alcohol, ether and chloroform.

ACTION

Although the precise mechanism of action of capsaicin is not fully understood, current evidence suggests that capsaicin renders skin and joints insensitive to pain by depleting and preventing reaccumulation of substance P in peripheral sensory neurons. Substance P is thought to be the principal chemomediator of pain impulses from the periphery to the central nervous system. In addition, substance P has been shown to be released into joint tissues and activate inflammatory mediators involved with the pathogenesis of rheumatoid arthritis.

INDICATION

Zostrix is indicated for the temporary relief of peripheral neuralgias such as the pain following shingles (herpes zoster). Zostrix is also indicated for the temporary relief of the pain associated with rheumatoid arthritis and osteoarthritis.

WARNINGS

FOR EXTERNAL USE ONLY. Avoid contact with eyes and broken or irritated skin. Do not bandage tightly. If condition worsens, or does not improve after 28 days, discontinue use of this product and consult your physician. **Keep this and all drugs out of the reach of children.** In case of accidental ingestion, seek professional assistance or contact a Poison Control Center immediately.

DIRECTIONS

Adults and children 2 years of age and older: Apply Zostrix to affected area 3 to 4 times daily. Transient burning may occur upon application, but usually disappears in 72 hours. Application schedules of less than 3 to 4 times a day may not provide optimum pain relief and the burning sensation may persist. **Wash hands immediately after applying Zostrix.**

PERMAX®
pergolide mesylate

An added dimension
in the treatment of
Parkinson's disease

An adjunct to levodopa/carbidopa in the management of patients with Parkinson's disease

- The first dopamine agonist indicated for Parkinson's disease with activity at both D_1 and D_2 receptors
- 10 to 1,000 times more potent than bromocriptine on a milligram-per-milligram basis
- Improves patients' functioning in activities of daily living, relieves signs and symptoms, and reduces "off" time
- May allow a significant reduction in levodopa dosage
- Most common adverse events were dyskinesia, nausea, dizziness, and hallucinations
- Hypotension may occur, especially early in the course of therapy
- Stepwise titration without regard to meals
- Available in 0.05-mg, 0.25-mg, and 1-mg scored tablets

Permax*

pergolide mesylate

Brief Summary. Consult the package insert for complete prescribing information.

Indications and Usage: Permax is indicated as adjunctive treatment to levodopa/carbidopa in the management of the signs and symptoms of Parkinson's disease.

Evidence to support the efficacy of pergolide mesylate as an antiparkinsonian adjunct was obtained in a multicenter study enrolling 376 patients with mild to moderate Parkinson's disease who were intolerant to levodopa/carbidopa as manifested by moderate to severe dyskinesia and/or on-off phenomena. On average, the sample of patients evaluated had been on levodopa/carbidopa for 3.9 years (range, two days to 16.8 years). The administration of pergolide mesylate permitted a 5% to 30% reduction in the daily dose of levodopa. On average, these patients treated with pergolide mesylate maintained an equivalent or better clinical status than they exhibited at baseline.

Contraindications: Pergolide mesylate is contraindicated in patients who are hypersensitive to this drug or other ergot derivatives.

Warnings: *Symptomatic Hypotension* —In clinical trials, approximately 10% of patients taking pergolide mesylate with levodopa vs 7% taking placebo with levodopa experienced symptomatic orthostatic and/or sustained hypotension, especially during initial treatment. With gradual dosage titration, tolerance to the hypotension usually develops. It is, therefore, important to warn patients of the risk, to begin therapy with low doses, and to increase the dosage in carefully adjusted increments over a period of three to four weeks.

Hallucinosis —In controlled trials, pergolide mesylate with levodopa caused hallucinosis in about 14% of patients as opposed to 3% taking placebo with levodopa. This was of sufficient severity to cause discontinuation of treatment in about 3% of those enrolled; tolerance to this untoward effect was not observed.

Fatalities —In the placebo-controlled trial, two of 187 patients treated with placebo died as compared with one of 189 patients treated with pergolide mesylate. Of the 2,299 patients treated with pergolide mesylate in premarketing studies evaluated as of October 1988, 143 died while on the drug or shortly after discontinuing the drug. The patient population under evaluation was elderly, ill, and at high risk for death. It seems unlikely that pergolide mesylate played any role in these deaths, but the possibility that pergolide shortens survival of patients cannot be excluded with absolute certainty.

In particular, a case-by-case review of the clinical course of the patients who died failed to disclose any unique set of signs, symptoms, or laboratory results that would suggest that treatment with pergolide caused their deaths. Sixty-eight percent (68%) of the patients who died were 65 years of age or over. No death (other than a suicide) occurred within the first month of treatment; most of the patients who died had been on pergolide for years. A relative frequency of the causes of death by organ system are: pulmonary failure/pneumonia, 35%; cardiovascular, 30%; cancer, 11%; unknown, 8.4%; infection, 3.5%; extrapyramidal syndrome, 3.5%; stroke, 2.1%; dysphagia, 2.1%; injury, 1.4%; suicide, 1.4%; dehydration, 0.7%; glomerulonephritis, 0.7%.

Precautions: *General* —Caution should be exercised when administering pergolide mesylate to patients prone to cardiac dysrhythmias.

In a study comparing pergolide mesylate and placebo, patients taking pergolide mesylate were found to have significantly more episodes of atrial premature contractions (APCs) and sinus tachycardia.

The use of pergolide mesylate in patients on levodopa may cause and/or exacerbate preexisting states of confusion and hallucinations (*see* Warnings). Also, the abrupt discontinuation of pergolide mesylate in patients receiving it chronically as an adjunct to levodopa may precipitate the onset of hallucinations and confusion; these may occur within a span of several days. Discontinuation of pergolide should be undertaken gradually whenever possible, even if the patient is to remain on levodopa.

The administration of pergolide mesylate to patients receiving levodopa may cause and/or exacerbate preexisting dyskinesia.

Information for Patients —Patients and their families should be informed of the common adverse consequences of the use of pergolide mesylate (*see* Adverse Reactions) and the risk of hypotension (*see* Warnings).

Patients should be advised to notify their physician if they become pregnant or intend to become pregnant during therapy.

Patients should be advised to notify their physician if they are breast feeding an infant.

Laboratory Tests —No specific laboratory tests are deemed essential for the management of patients on Permax. Periodic routine evaluation of all patients, however, is appropriate.

Drug Interactions —Dopamine antagonists, such as the neuroleptics (phenothiazines, butyrophenones, thioxanthines) or metoclopramide, ordinarily should not be administered concurrently with Permax (a dopamine agonist); these agents may diminish the effectiveness of Permax.

Because pergolide mesylate is approximately 90% associated with plasma proteins, caution should be exercised if pergolide mesylate is coadministered with other drugs known to affect protein binding.

Carcinogenesis, Mutagenesis, and Impairment of Fertility —A two-year carcinogenicity study was conducted in mice using dietary levels of pergolide mesylate equivalent to oral doses of 0.6, 3.7, and 36.4 mg/kg/day in males and 0.6, 4.4, and 40.8 mg/kg/day in females. A two-year study in rats was conducted using dietary levels equivalent to oral doses of 0.04, 0.18, and 0.88 mg/kg/day in males and 0.05, 0.28, and 1.42 mg/kg/day in females. The highest doses tested in the mice and rats were approximately 340 and 12 times the maximum human oral dose administered in controlled clinical trials (6 mg/day equivalent to 0.12 mg/kg/day).

A low incidence of uterine neoplasms occurred in both rats and mice. Endometrial adenomas and carcinomas were observed in rats. Endometrial sarcomas were observed in mice. The occurrence of these neoplasms is probably attributable to the high estrogen/progesterone ratio which would occur in rodents as a result of the prolactin-inhibiting action of pergolide mesylate. The endocrine mechanisms believed to be involved in the rodents are not present in humans. However, even though there is no known correlation between uterine malignancies occurring in pergolide-treated rodents and human risk, there are no human data to substantiate this conclusion.

Pergolide mesylate was evaluated for mutagenic potential in a battery of tests that included an Ames bacterial mutation assay, a DNA repair assay in cultured rat hepatocytes, a point-mutation assay in cultured L5178Y cells, and a determination of chromosome alteration in bone marrow cells of Chinese hamsters. A weak mutagenic response was noted in the in vitro mammalian cell-point-mutation assay using L5178Y cells only after metabolic activation with rat liver microsomes. No mutagenic effects were obtained in the two other in vitro assays and in the in vivo assay. The relevance of these findings to humans is unknown.

A fertility study in male and female mice showed that fertility was maintained at 0.6 and 1.7 mg/kg/day but decreased at 5.6 mg/kg/day. Prolactin has been reported to be involved in stimulating and maintaining progesterone levels required for implantation in mice and, therefore, the impaired fertility at high dose may occur because of depressed prolactin levels.

Usage in Pregnancy—Pregnancy Category B —Reproduction studies were conducted in mice at doses of 5, 16, and 45 mg/kg/day and in rabbits at doses of 2, 6, and 16 mg/kg/day. The highest doses tested in mice and rabbits were 375 and 133 times the 6 mg/day maximum human dose administered in controlled clinical trials. In these studies, there was no evidence of harm to the fetus due to pergolide mesylate.

© 1991, ELI LILLY AND COMPANY

There are, however, no adequate and well-controlled studies in pregnant women. Among women who received pergolide mesylate for endocrine disorders in premarketing studies, there were 33 pregnancies that resulted in healthy babies and four pregnancies that resulted in congenital abnormalities (two major, two minor); a causal relationship has not been established. Because human data are limited and because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers —It is not known whether this drug is excreted in human milk. The pharmacologic action of pergolide mesylate suggests that it may interfere with lactation. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions to pergolide mesylate in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use —Safety and effectiveness in children have not been established.

Adverse Reactions: *Commonly Observed* —In premarketing clinical trials, the most commonly observed adverse events associated with use of pergolide mesylate which were not seen at an equivalent incidence among placebo-treated patients were: nervous system complaints, including dyskinesia, hallucinations, somnolence, insomnia; digestive complaints, including nausea, constipation, diarrhea, dyspepsia; and respiratory system complaints, including rhinitis.

Associated With Discontinuation of Treatment —Twenty-seven percent (27%) of approximately 1,200 patients receiving pergolide mesylate for treatment of Parkinson's disease in premarketing clinical trials in the US and Canada discontinued treatment due to adverse events. The events most commonly causing discontinuation were related to the nervous system (15.5%), primarily hallucinations (7.8%) and confusion (1.8%).

Fatalities —*See* Warnings.

Incidence in Controlled Clinical Trials —The table that follows enumerates adverse events that occurred at a frequency of 1% or more among patients taking pergolide mesylate who participated in the premarketing controlled clinical trials comparing pergolide mesylate with placebo. In a double-blind, controlled study of six months' duration, patients with Parkinson's disease were continued on levodopa/carbidopa and were randomly assigned to receive either pergolide mesylate or placebo as additional therapy.

The prescriber should be aware that these figures cannot be used to predict the incidence of side effects in the course of usual medical practice where patient characteristics and other factors differ from those which prevailed in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other clinical investigations involving different treatments, uses, and investigators. The cited figures, however, do provide the prescribing physician with some basis for estimating the relative contribution of drug and nondrug factors to the side-effect incidence rate in the population studied.

Incidence of Treatment-Emergent Adverse Experiences in the Placebo-Controlled Clinical Trial

*Events reported by at least 1% of patients receiving pergolide mesylate are included.

Events Observed During the Premarketing Evaluation of Permax —This section reports event frequencies evaluated as of October 1988 for adverse events ocurring in a group of approximately 1,800 patients who took multiple doses of pergolide mesylate. The conditions and duration of exposure to pergolide mesylate varied greatly, involving well-controlled studies as well as experience in open and uncontrolled clinical settings. In the absence of appropriate controls in some of the studies, a causal relationship between these events and treatment with pergolide mesylate cannot be determined.

The following enumeration by organ system describes events in terms of their relative frequency of reporting in the data base. Events of major clinical importance are also described in the Warnings and Precautions sections.

The following definitions of frequency are used: frequent adverse events are defined as those occurring in at least 1/100 patients; infrequent adverse events are those occurring in 1/100 to 1/1,000 patients; rare events are those occurring in fewer than 1/1,000 patients.

Body as a Whole —*Frequent:* headache, asthenia, accidental injury, abdominal pain, chest pain, back pain, flu syndrome, neck pain, fever; *Infrequent:* facial edema, chills, enlarged abdomen, malaise, neoplasm, hernia, pelvic pain, sepsis, cellulitis, moniliasis, abscess, jaw pain, hypothermia; *Rare:* acute abdominal syndrome, LE syndrome.

Cardiovascular System —*Frequent:* postural hypotension, syncope, hypertension, palpitations, vasodilatations, congestive heart failure; *Infrequent:* myocardial infarction, tachycardia, heart arrest, abnormal electrocardiogram, angina pectoris, thrombophlebitis, bradycardia, ventricular extrasystoles, cerebrovascular accident, ventricular tachycardia, cerebral ischemia, atrial fibrillation, varicose vein, pulmonary embolus, AV block, shock; *Rare:* vasculitis, pulmonary hypertension, pericarditis, migraine, heart block, cerebral hemorrhage.

Digestive System —*Frequent:* nausea, vomiting, dyspepsia, diarrhea, constipation, dry mouth, dysphagia; *Infrequent:* flatulence, abnormal liver function tests, increased appetite, salivary gland enlargement, thirst, gastroenteritis, gastritis, periodontal abscess, intestinal obstruction, nausea and vomiting, gingivitis, esophagitis, cholelithiasis, tooth caries, hepatitis, stomach ulcer, melena, hepatomegaly, hematemesis, eructation; *Rare:* sialadenitis, peptic ulcer, pancreatitis, jaundice, glossitis, fecal incontinence, duodenitis, colitis, cholecystitis, aphthous stomatitis, esophageal ulcer.

Endocrine System —*Infrequent:* hypothyroidism, adenoma, diabetes mellitus, ADH inappropriate; *Rare:* endocrine disorder, thyroid adenoma.

Hemic and Lymphatic System —*Frequent:* anemia; *Infrequent:* leukopenia, lymphadenopathy, leukocytosis, thrombocytopenia, petechia, megaloblastic anemia, cyanosis; *Rare:* purpura, lymphocytosis, eosinophilia, thrombocythemia, acute lymphoblastic leukemia, polycythemia, splenomegaly.

Metabolic and Nutritional System —*Frequent:* peripheral edema, weight loss, weight gain; *Infrequent:* dehydration, hypokalemia, hypoglycemia, iron deficiency anemia, hyperglycemia, gout, hypercholesteremia; *Rare:* electrolyte imbalance, cachexia, acidosis, hyperuricemia.

Musculoskeletal System —*Frequent:* twitching, myalgia, arthralgia; *Infrequent:* bone pain, tenosynovitis, myositis, bone sarcoma, arthritis; *Rare:* osteoporosis, muscle atrophy, osteomyelitis.

Nervous System —*Frequent:* dyskinesia, dizziness, hallucinations, confusion, somnolence, insomnia, dystonia, paresthesia, depression, anxiety, tremor, akinesia, extrapyramidal syndrome, abnormal gait, abnormal dreams, incoordination, psychosis, personality disorder, nervousness, choreoathetosis, amnesia, paranoid reaction, abnormal thinking; *Infrequent:* akathisia, neuropathy, neuralgia, hypertonia, delusion, convulsion, libido increased, euphoria, emotional lability, libido decreased, vertigo, myoclonus, coma, apathy, paralysis, neurosis, hyperkinesia, ataxia, acute brain syndrome, torticollis, meningitis, manic reaction, hypokinesia, hostility, agitation, hypotonia; *Rare:* stupor, neuritis, intracranial hypertension, hemiplegia, facial paralysis, brain edema, myelitis, hallucinations and confusion after abrupt discontinuation.

Respiratory System —*Frequent:* rhinitis, dyspnea, pneumonia, pharyngitis, cough increased; *Infrequent:* epistaxis, hiccup, sinusitis, bronchitis, voice alteration, hemoptysis, asthma, lung edema, pleural effusion, laryngitis, emphysema, apnea, hyperventilation; *Rare:* pneumothorax, lung fibrosis, larynx edema, hypoxia, hypoventilation, hemothorax, carcinoma of lung.

Skin and Appendages System —*Frequent:* sweating, rash; *Infrequent:* skin discoloration, pruritus, acne, skin ulcer, alopecia, dry skin, skin carcinoma, seborrhea, hirsutism, herpes simplex, eczema, fungal dermatitis, herpes zoster; *Rare:* vesiculobullous rash, subcutaneous nodule, skin nodule, skin benign neoplasm, lichenoid dermatitis.

Special Senses System —*Frequent:* diplopia; *Infrequent:* otitis media, conjunctivitis, tinnitus, deafness, taste perversion, ear pain, eye pain, glaucoma, eye hemorrhage, photophobia, visual field defect; *Rare:* blindness, cataract, retinal detachment, retinal vascular disorder.

Urogenital System —*Frequent:* urinary tract infection, urinary frequency, urinary incontinence, hematuria, dysmenorrhea; *Infrequent:* dysuria, breast pain, menorrhagia, impotence, cystitis, urinary retention, abortion, vaginal hemorrhage, vaginitis, priapism, kidney calculus, fibrocystic breast, lactation, uterine hemorrhage, urolithiasis, salpingitis, pyuria, metrorrhagia, menopause, kidney failure, breast carcinoma, cervical carcinoma; *Rare:* amenorrhea, bladder carcinoma, breast engorgement, epididymitis, hypogonadism, leukorrhea, nephrosis, pyelonephritis, urethral pain, uricaciduria, withdrawal bleeding.

Books

Advances in Neurology, vol 53, Parkinson's Disease: Anatomy, Pathology, and Therapy, edited by M. B. Streifler, A. D. Korczyn, E. Melamed, and M. B. H. Youdin, 624 pp, $125, New York, NY, Raven Press, 1990.

Although the title of this book is not inaccurate, it may be somewhat misleading. Rather than being a comprehensive text on Parkinson's disease, it is a collection of almost 90 papers from the Ninth International Symposium on Parkinson's Disease held in Jerusalem, Israel, in June 1988. As such, it probably has little appeal for medical students, nonneurologists, or, possibly, even general neurologists. On the other hand, for those of us with an interest in Parkinson's disease, this book provides a wonderfully diverse smorgasbord of recent clinical and neurobiological research topics related to Parkinson's disease and the basal ganglia.

The papers in this collection are parceled into the following seven sections: "Normal and Pathological Anatomy," "Neurochemistry and Pharmacology," "Neurophysiology," "Toxicology and Environment," "Clinical Aspects," "Current Therapy and Side Effects," and "Therapeutic Research and Developments." The length of the contributions ranges from four to 16 pages and, as might be expected in a collection of this type, they vary in quality. Even though the information in this book is at least 2½ years old at the time of this review, it is surprisingly up to date, especially considering the pace at which research in this field is advancing.

Papers by Graybiel et al and Gibb et al report recent pathologic studies examining the relationship between neuromelanin and selective vulnerability of nigral neurons. The current controversy in this area of investigation is highlighted by the fact that the groups' findings and conclusions are diametrically opposed; the role of melanin remains unclear. The methylphenyltetrahydropyridine (MPTP) model of Parkinson's disease and the mechanism of action of MPTP are the subjects of eight papers. Notably, the International Symposium took place before reports on the defect in complex I of the mitochondrial electron-transport chain had been published, so there is no information on this exciting topic in the book. There are numerous excellent clinical papers dealing with Parkinson's disease and related disorders. A concise and convincing argument for uniform research diagnostic criteria for Parkinson's disease is made by Ward and Gibb. Koller and Findley provide a succinct review of psychogenic tremor, including diagnostic criteria. Several papers discuss the use of deprenyl (Eldepryl) in Parkinson's disease, and Haefely et al discuss the properties of Ro 19-6327, a new, reversible, highly selective monoamine oxidase-B inhibitor that is presently under clinical investigation by the Parkinson Study Group. As might be anticipated, there are four papers on experimental and therapeutic transplantation.

In summary, this volume will be a valuable addition to the libraries of neurologists and neurobiologists interested in recent advances in the pathology, neurochemistry, clinical aspects, and experimental therapeutics of Parkinson's disease and related disorders. It will be less useful for medical students and nonneurologists.

J. Timothy Greenamyre, MD, PhD
Rochester, NY

Neurobehavioral Aspects of Multiple Sclerosis, edited by S. M. Rao, 271 pp, with illus, $39.95, New York, NY, Oxford University Press Inc, 1990.

This small monograph, with contributions by 28 authors, focuses on cognitive and affective alterations in multiple sclerosis (MS). It is divided into four parts: clinicopathological features (84 pages), cognitive dysfunction (91 pages), affective disturbance in MS (35 pages), and management of neurobehavioral dysfunction (52 pages). It is correctly pointed out in the introduction that cognitive dysfunction in MS tends to be overlooked or discounted by physicians. On the other hand, this is often less because of lack of awareness and disinterest and more because of the desire to lighten the already burdensome knowledge of having a disabling neurological disorder. There are situations in which the identification of cognitive impairment in MS is not necessarily to the patient's advantage (eg, custody battles for children). However, the innate variability of human behavior requires a considerable latitude in determining what and how patients should be told about cognitive dysfunction. Furthermore, health professionals need to know the facts in the first place. This book aims at a more complete understanding of behavioral abnormalities in MS and admirably summarizes the rather disparate literature on this topic. The chapters on diagnosis, clinical course, and imaging are certainly not definitive but give readable and concise surveys. The chapter on subcortical dementia appears to perpetuate the long-standing and erroneous assumption that MS does not involve the cerebral cortex. The chapters on memory, cognitive dysfunction, and affected disturbance constitute an excellent synthesis and summary of the present state of knowledge. The long-standing debate on the role of stress in MS is ably reviewed by Warren.

The book is directed toward the multidisciplinary audience, a daunting task in which it succeeds well. It serves to illustrate the necessity for a multidisciplinary approach in the comprehensive management of a patient with MS. It should make worthwhile reading for neurologists, psychiatrists, neuropsychologists, and other health care professionals who see substantial numbers of patients with MS.

Avances y Controversias en el Diagnóstico y en el Tratamiento de la Pathologia Vascular Cerebral Isquémica, edited by M. Aguilar Barberá, A. Arboix Damunt, L. I. Soler Singlá, Barcelona, Spain, Edika Medica SA, 1989.

This volume represents a compilation of papers presented at the International Symposium on Ischemic Cerebrovascular Pathology held by the Societat Catalana de Neurologia in Tarragona, Spain, in 1989.

The volume opens, with the only chapter written in English, on selected aspects of human and experimental stroke. Subsequent chapters contain a number of relevant topics related to diagnostic, pathologic, and therapeutic aspects of ischemic cerebrovascular disease. There are interesting contributions on the local and regional strategies regarding care services for patients with acute stroke. Another chapter summarizes a discussion on vascular dementias and brain-heart interactions.

The book is well written, easy to read, and most sections are clearly organized and referenced. Although much of the information presented is well known, the chapters serve as useful review. Overall, controversial points are presented in a well-balanced manner. Like many published reports of conference proceedings, this volume suffers from an uneven quality of the contributions.

All in all, any clinician who regularly takes care of patients with stroke will find this volume helpful and informative.

José Biller, MD

Neurofibromatosis: A Handbook for Patients, Families, and Health Care Professionals, edited by Allan E. Rubenstein and Bruce R. Korf, 256 pp, with illus, $63, New York, NY: Thieme Medical Publishers Inc, 1990.

In recent years, our knowledge of neurofibromatosis (NF) has expanded significantly. The location of the NF gene on chromosome 17, for NF 1, and chromosome 22, for NF 2, has been identified, and the clinical variations of the disorder have been more fully delineated. The book was sponsored by the National Neurofibromatosis Foundation, New York, NY, and the approach is varied, with some information written for the layperson and other topics more detailed and professionally oriented. The book is multiauthored and brings together the existing information about NF as of early 1990. It is divided into four sections: "Medical," "Genetic," and "Psychosocial Aspects," and "Appendices." There are 20 chapters covering most of the major areas of concern. Following the introduction and history, there are chapters on diagnosis, neurological aspects, ocular features, NF and cancer, molecular genetics, psychosocial aspects, and many other areas. The chapter organization makes it easy to find information on any subject of interest. The book is filled with useful information, and each chapter is well referenced. The appendix contains information on the National Neurofibromatosis Foundation and a listing of their chapters, along with NF clinics and centers in the United States and Canada.

An effort is made to make material understandable to the layperson, but there is also an effort to be comprehensive and accurate. The authors avoid any dogmatic approach to therapy or standardized follow-up and repeatedly emphasize the importance of evaluating each person individually and using clinical judgment.

The book is well illustrated, attractive, and easy to read. There are numerous tables that outline diagnostic criteria and complications. The myriad of these complications that can or might occur with NF are carefully detailed by multiple authors. Repeatedly, these authors comment that the percentage of patients who have these complications is small, but it is page 176 before Dr Carey states that "more than half of all people with NF will only have café au lait spots and cutaneous neurofibromas. The remaining 30% to 40% of individuals will have one or more of the more medically serious complications. . . . " In a book for patients and families, some might be very anxious by the time they reach this reassuring information.

I found it an excellent overview of NF for health care professionals and can recommend it to them. It will also be helpful to families and patients if it is combined with counseling from knowledgeable professionals or the national organization. It provides a handy source of information for anyone working with individuals who have this complex disorder.

Gary J. Myers, MD

Peripheral Nerve Lesions, edited by M. Mumenthaler and H. Schliack, 416 pp, with illus, $95, New York, NY, Thieme Medical Publishers Inc, 1991.

This 400-page book, mostly on focal peripheral nerve lesions and their treatment, is the "revised translation (Sibylle A. Wallace, pediatric neurologist, Mount Sinai School of Medicine [New York, NY]) from the [fifth] German edition, published and copyrighted in 1987."

The book is logically organized with sequential sections on nerve embryology, anatomy, histopathology, classification of traumatic lesions, biomechanics, physiology, clinical examination, electrophysiologic examination, and operative treatment, and followed by specific sections on roots, plexus, and peripheral nerves. At least four major books on this subject are now in print, several written by orthopedists. In comparison with these other books, this one has approximately the same number of pages but contains more information. It is a scholarly work with extensive references. It has many line drawings, generally of reasonable quality. Because it is comprehensive, compact, well-referenced, and authoritative, it can be recommended with considerable enthusiasm.

The book has weaknesses too. Too frequently, pseudoscientific expressions are used instead of simple descriptions. Patients do not "complain of brachialgia paresthetic nocturna." Presumably, the translator was trying to convey the author's precise meaning, but too often the sentences are long, heavy, and not illuminating. The illustrations also are not always the best. Some of the old illustrations should have been replaced by new and better ones. Why, for example, are we not shown a magnetic resonance scan of a synovial cyst compressing the peroneal nerve? Perhaps the greatest weakness of the book is that it insufficiently focuses on unsolved problems. Our ignorance of underlying pathophysiologic mechanisms is not emphasized. Although this book has sections on neurobiology and neuropathology, it is unclear how they might help resolve some of the clinical problems. Important new insights have been gained in how nerves react to compression and of how fibers regenerate, or do not, depending on species, site, nature of lesion, and a variety of other risk factors.

Peter J. Dyck, MD
Rochester, Minn

Neuro-Oncology: Primary Malignant Brain Tumors, edited by D. G. T. Thomas, 303 pp, $62.50, Baltimore, Md, The Johns Hopkins University Press, 1990.

Thomas and 24 contributors set out to write a thorough, authoritative, contemporary text on primary malignant brain tumors for postgraduate clinicians and basic scientists interested in neuro-oncology. By and large, they have succeeded. The book is certainly thorough, containing chapters on clinical manifestations, epidemiology, imaging, pathology, treatment, relevant basic sciences, and terminal care of patients with brain tumor. The chapter by Thomas and McKeran, "Clinical Manifestations of Brain Tumors," is appropriate for students but seems out of place in a book intended for a neurologically sophisticated audience. The chapter on biological response modifiers is too long and needs a discussion of adrenocorticosteroid therapy for patients with brain tumor. The book is authoritative with contributions by many leading investigators, including an outstanding chapter on "Radiotherapy in the Treatment of Cerebral Astrocytomas" by Leibel and Sheline. The book is not entirely up-to-date, but this, of course, is the Achilles' heel of any text. For example, the discussion of tumor-suppressor genes (ie, antioncogenes) as they pertain to the genesis and progression of glioma is deficient by 1991 standards, unfortunate because the chapter on molecular genetics by Westermark et al is splendid otherwise. Similarily, the concise, thoughtful contribution by Dropcho and Mahaley on

"Chemotherapy for Malignant Glioma in Adults" is not current, missing several recent references to successful chemotherapy for specific malignant glioma subtypes. If the chapter on clinical manifestations of brain tumor is included in future editions, the tables should be updated. They are taken from an article published before the modern computed tomographic and magnetic resonance era (eg, a diagnosis of papilledema diagnosis in 52% of cases). Like most multiauthored books, duplications and omissions are present, but, to his credit, Thomas, by careful editing, has managed to keep both to a minimum. May I suggest the next edition of this text be renamed "Neuro-Oncology: Glioma" and the content focused accordingly? Alternatively, the title may be maintained and the content expanded to include certain malignant brain tumors omitted from this edition (eg, primary cerebral lymphoma and malignant meningioma).

The strengths of this text far outweigh its weaknesses. It is a valuable reference text in its current form, and I look forward to future editions.

J. Gregory Cairncross, MD
London, Ontario

Essentials of Neurology, ed 6, edited by Lord Walton, 339 pp, $33, New York, NY, Churchill-Livingstone Inc, 1989.

That a book can go through six editions speaks to some degree for its quality.

Essentials of Neurology continues to be a good book. It is not extensive enough to be a reference and not oriented toward pathophysiology, so it cannot be considered a basic text for students. It is predominantly a primer of the phenomenology of clinical neurology; an elaboration of basic principles of evaluation of the nervous system with an overview of the major entities (systems, signs, and broad disease categories).

The audience should be the resident in internal medicine, the primary physician, and, possibly, also the beginning neurology resident. The text is more extensive than past editions but appears not much larger, probably because of the reduction in the size of the print; it is fortunate that youngsters with good eyes will be the main audience.

The motivated trainee will find this book a good starter and, it is hoped, will be stimulated to delve deeper into more extensive sources for the specifics.

Myoblast Transfer Therapy, vol 280, **Advances in Experimental Medicine and Biology,** edited by R.C. Griggs and G. Karpati, 316 pp, with illus, $79.50, New York, NY, Plenum Press, 1990.

Myoblast transfer represents an early exploitation in a therapeutic venture based on the tremendous advances made by molecular genetics. The possibility and promise of myoblast transfer therapy in the treatment of Duchenne muscular dystrophy and other inherited forms of muscle disease has raised the hopes and expectations of the public and, especially, affected individuals and their families.

This volume, a compilation of 35 presentations made at the International Conference on Myoblast Transfer Therapy in June 1989, is conveniently organized into seven general-topic sections relevant to myoblast therapy. The individual articles, which are well-written, short, and focused, present a realistic assessment of the challenges that will need to be addressed and mastered before myoblast transfer therapy can ever become "standard therapy." The discussions that follow individual articles and each general-topic section are very enlightening as they highlight many of the practical concerns and unresolved questions regarding myoblast transfer therapy.

The reader will find that this book successfully separates the science fiction from the fact associated with myoblast transfer. Therefore, clinicians who regularly care for and thus serve as medical interpreters for patients with muscle disease and their families would find this volume extremely useful. Historically, this volume provides a succinct but comprehensive snapshot of current scientific understanding in an exciting area of medicine, at a juncture when advances in molecular genetics are being initially applied to novel therapeutic techniques.

Jack E. Riggs, MD
Morgantown, WVa

Post-Polio Syndrome, edited by Theodore L. Munsat, 121 pp, with illus, $44.95, Boston, Mass, Butterworth-Heinemann, 1991.

This volume represents a concise collection of useful information on the so-called post-polio syndrome, a somewhat poorly understood disorder leading to disability many years after acute poliomyelitis. The emphasis of each chapter varies, and it will be helpful to physiatrists, neurologists, orthopedists, physical therapists, and sufferers themselves.

This book has 10 chapters. The first represents a general introduction with some historical notes. The second chapter discusses basic molecular biology and virology. The fourth chapter is also primarily basic science, dealing with the pathology of muscle and spinal cord in both acute poliomyelitis and the post-polio syndrome. The third chapter is more clinically oriented, giving a general definition of the post-polio syndrome and describing clinical features. Chapters 5 and 6 deal primarily with the electrophysiology of the syndrome, including electromyography, single-fiber electromyography, and macroelectromyography. Some discussion of muscle biopsy is also included. Chapter 7 is once again more clinically oriented with the discussion of strength measurement. The eighth chapter, by a physical therapist, deals with rehabilitation. This is quite good but, unfortunately, somewhat too short. Chapters 9 and 10 are written by survivors of poliomyelitis who have been active in the effort to educate not only other survivors of the disease but also the medical community.

The strengths of the book depend on the interest of the reader. For basic scientists or researchers, chapters 4 through 6 on pathology and electrophysiology are quite good and review all significant investigations to date. For the clinically minded, chapters 3 and 7 are excellent. For the poliomyelitis survivor, the chapters on history and rehabilitation are of interest. Also, the last two chapters on support groups and community resources could be quite helpful. The illustrations and tables are generally concise and organized. References are extensive.

This book is somewhat lacking in several areas. No adequate discussion is presented of the long-term orthopedic complications of poliomyelitis, which certainly can be regarded as a manifestation of the post-polio syndrome. The excellent chapter on rehabilitation is too short and not detailed enough. No emphasis is placed on issues of differential diagnosis, as many of the symptoms of post-polio syndrome are vague and can mimic those of a variety of other medical illnesses. This is quite important in that treatable illness should not be overlooked and ascribed to old poliomyelitis. Finally, by virtue of having multiple authors, material is unduly repeated.

In summary, this volume represents a valuable, concise resource for medical practitioners in a variety of disciplines who are exposed to patients with the late effects of poliomyelitis. It also should be a valuable reference for patients themselves.

Letters to the Editor

Letters to the editor should be submitted as an original and two duplicates. They should be typewritten double-spaced on plain bond paper; they will be subject to editing. If they are prepared on a word processor, do not justify the right margin. A copyright transmittal letter signed by all authors must accompany this (see "Instructions for Authors").

Delayed Varicella Vasculopathy

To the Editor.—I read with great interest the article by Caekebeke et al.[1] They carefully document a case of a 5-year-old boy who suffered from an acute hemiparesis 3 and 9 months after a chickenpox infection.

However, I disagree with their contention that this association had not been previously reported. Earlier, Holmes and I[2] described a 3½-year-old boy who developed a hemiparesis 1 month after a varicella infection. Eda et al[3] in 1983 had already reported four similar cases, and then Kamholz and Tremblay[4] documented another. The ages of the six patients[2-4] ranged from 1 to 6 years of age, and the time between onset of varicella and onset of hemiparesis varied from 1 to 3 months. Cranial imaging studies revealed infarcts involving the basal ganglia and internal capsule in all six cases. Caekebeke and coworkers' patient[1] differs slightly because he had two events at 3 and 9 months after varicella infection, and his infarct involved the left putamen as well as the left temporal lobe.

Their statement that acute childhood hemiplegia was not a known complication of zoster infection is also incorrect. Walker et al[5] described a 7-year-old boy with herpes zoster ophthalmicus and contralateral hemiplegia; his angiogram showed multiple areas of narrowing in the proximal anterior and middle cerebral arteries.

By documenting intrathecal synthesis of varicella zoster virus IgG and IgA in addition to abnormalities in the magnetic resonance image and cerebral angiogram, Caekebeke et al[1] have described their patient in more detail than any of the previously reported cases. Theirs is, therefore, the most convincing. However, they are not the first authors to describe this association between varicella and a delayed hemiparesis.

5. Walker RJ, Gammal TE, Allen MB. Cranial arteritis associated with herpes zoster: case report with angiographic findings. *Radiology.* 1973;107:109-110.

In Reply.—Dr Liu is correct: we missed earlier reports on the association between chickenpox and acute hemiparesis in childhood. Recently, another case was described by Shuper et al.[1] This 7.5-year-old boy developed a right hemiplegia and aphasia 10 weeks after contracting chickenpox. He presented again 7 months later with an acute exacerbation of seizures. Cerebral angiography showed evidence of focal vasculitis.

The presumed association of primary varicella zoster virus infection and vasculitis rests on the temporal occurrence and on the demonstration of an intrathecal varicella zoster virus-specific IgG response. However, oligoclonal bands can still be demonstrated several months after an uncomplicated varicella zoster virus meningitis and do not provide definite evidence for active infection.[2] Definite proof of the linkage between primary varicella zoster virus infection and vasculitis can only be obtained by cerebral biopsy, which is not indicated in these patients, or by an autopsy.

In clinical practice, physicians facing a child with an acute hemiparesis should carefully ask about a history of antecedent chickenpox. The management in these varicella zoster virus-associated cases is still open: steroids, acyclovir, or no medication at all?

Fetal Homotransplants in the Treatment of Parkinson's Disease

To the Editor.—The article by Madrazo et al[1] represents an analysis of seven patients who underwent embryonic nigral and adrenal transplants for the treatment of Parkinson's disease. We note that donor neuronal tissue used for this study was derived from spontaneous abortions. There are several problems associated with the use of tissue obtained from spontaneous as opposed to elective abortion for use in neural grafting. These include the following:

1. Chromosomal abnormalities are present in 20% to 50% of cases of spontaneous abortion.[2]
2. Infectious agents that are associated with spontaneous abortions may increase the risk of a transplant-related infection.[3]
3. There is an increased likelihood of bacterial contamination in donor material obtained at the time of spontaneous abortion due to the direct passage of the fetus through the vaginal canal. In elective abortions there is a high likelihood that tissue can be procured steriley.[4,5] In this regard, one wonders if the brain abscess and bone flap infections in patient number three were not transplant derived rather than a consequence of immunosuppression as the authors suggest. Information regarding the type of organism and the exact location of the brain abscess might help in clarifying this issue.
4. The majority of spontaneous abortions are preceded by fetal death in utero, which substantially reduces the likelihood of obtaining a viable graft.[6,7]

5. Spontaneous abortions are frequently associated with fetuses that are abnormally small, making staging difficult.[8]
6. Central nervous system defects are frequently associated with spontaneous abortions.[8]
7. Spontaneous abortions occur unpredictably making the timing of the surgical procedure and serological testing for human immunodeficiency virus, hepatitis, cytomegalovirus, and herpes in both the mother and fetus logistically difficult.
8. The authors employed ventral mesencephalon from only one fetus per patient. Pharmacologic analyses of the human striatum suggest that multiple donors (three to four) are necessary in order to provide sufficient concentrations of dopaminergic neurons to obtain the desired clinical effect.[4] Elective abortions provide a better opportunity to procure tissue from multiple donors.

The age of the donor also appears to be critically related to the likelihood of graft survival.[9] The optimal period for transplantation is thought to occur during the period of dopaminergic neuronal development and migration, but before the period of axonal extension.[9] This period of development occurs in the human embryo between postconception weeks 6.5 and 8.0.[10-12] Both solid and suspension grafts are most likely to be viable when tissue is derived from this period.[11,13] Madrazo used solid transplants derived from donors age postconception week 11 to 12. There is no laboratory data to the best of our knowledge that indicates that there is significant survival of dopamine neurons in human grafts of the age used in this study. Further, it is not clear how the embryonic age was determined. It should be noted that if dating is based on maternal record of last menstrual period, it is frequently inaccurate.[14]

There are several additional points that cause us to question whether the benefits reported from this procedure are due to some other mechanism such as the release of trophic factors.[15] The initial clinical improvement occurred between 4 and 8 weeks after transplantation. This is more rapid than would be expected if improvement were due to neuronal outgrowth of dopaminergic neurons.[13] Both dopaminergic- and nondopaminergic-mediated symptoms are reported to have improved. The graft was placed into the caudate nucleus, which is thought to have less influence than the putamen on dopaminergically mediated motor abnormalities of Parkinson's disease.[16] The time course of improvement parallels that observed in patients following autologous adrenal transplants where graft survival has been notably poor.[17,18] Finally, the best results were obtained in patients who received grafts derived from the oldest donors, which are the grafts least likely to survive.

On the other hand, if the benefits observed are the result of the elaboration of dopamine and neuronal connections from grafted cells, then based on such scientific evidence as currently exists, it is reasonable to suspect that transplantation of a larger number of younger fetuses obtained from women undergoing voluntary abortions may provide further clinical improvement.

In Reply.—We appreciate Freeman and Olanow's comments to our recent article on fetal brain homotransplantation for the treatment of Parkinson's disease (PD).[1] In relation to their concern for our use of fetal tissue obtained from spontaneous abortions for neural grafting, as opposed to elective abortions, we are in complete agreement with their arguments favoring elective abortions as a source of fetal tissue. In Mexico, however, we are limited to the use of fetuses only from spontaneous abortions, because elective abortions are illegal. We realize the complexity and multiple drawbacks involved, but have found this to be our only alternative for obtaining human fetal tissue in order to start the development of human fetal-human brain transplantations. We encourage those neural transplantation groups in countries where elective abortions are legal, to take advantage of their social circumstance, and thereby avoid the biological shortcomings that Freeman and Olanow enlisted in their letter.

Regarding the use of tissue from only one fetus, we[1] and others[2-6] have found this amount of unmanipulated tissue to give clinical benefit to the patients. Also, the immunologic challenge to the host is obviously less than would be expected from the use of tissue from more donors. The infection in patient number three is unlikely to be derived from the transplant, because it clearly started on the bone flap.

The viability and age of the fetuses were determined by in utero ultrasonography performed at the time abortion was diagnosed as imminent by the gynecologist who was unrelated to our transplantation group. Regarding the survival of dopamine neurons in fetal human grafts of 13 to 14 weeks' gestational age, there is neuropathologic evidence of their survival after human brain transplantation.[6]

The clinical response to fetal brain transplantation is good evidence of the probable relevance and interrelationship of all known mechanisms of action (local release of neurotransmitters, trophism, conectivity, etc.) of brain grafting procedures in the effectiveness of neural grafting. The possible therapeutic value of the different grafts is apparent from the evident differential clinical responses seen in our different groups of autotransplanted and homotransplanted parkinsonian subjects.[7]

Psychiatric Effects of Selegiline

To the Editor.—The exciting news that selegiline (deprenyl, Eldepryl) may retard the progression of early Parkinson's disease,[1,2] accompanied by the observation that few significant adverse effects were observed in these studies, has led physicians to treat many of their Parkinson's disease patients with this drug. This report concerns adverse psychiatric effects seen in my referral population of patients with Parkinson's disease. Over the last year, we have started selegiline therapy in approximately 60 patients, almost all of whom were both on multiple other antiparkinsonian medications and known to me for some time prior to this treatment. I have not included adverse effects that could be ameliorated by reduction of the dose of carbidopa/levodopa.

Apparent adverse effects in the younger population were most common in physically small patients, especially women. Five otherwise healthy women in their 40s and 50s developed adverse effects, although only two of these had a prior psychiatric history. All were taking carbidopa/levodopa. Three women (ages 41, 46, and 46 years, respectively) became hypomanic, with racing thoughts, mild paranoia, and markedly reduced sleep. Two women almost lost their jobs because of these changes. One woman who became promiscuous as well had a prior history compatible with cyclothymia, but had never been treated for this. In these three patients, the symptoms abated with lowering the dosage to 2.5 to 5 mg/d.

Two women became psychotic. A 48-year-old woman was taking multiple other antiparkinsonian medications and had a prior history of psychiatric hospitalization. She became floridly psychotic with organized and tenacious delusions and paranoia 3 months after selegiline was added, in the absence of other drug changes; the patient remained psychotic for 1 year. The last woman, aged 53 years, was seen by us after becoming floridly manic and psychotic soon after beginning selegiline therapy for very mild parkinsonism and was still hospitalized and psychotic 6 months after discontinuation of selegiline. She also had a history compatible with, but not diagnosed as, cyclothymia.

In the elderly, adverse psychiatric effects were most commonly seen in patients with some evidence of dementia. Several men who had behavioral problems with inappropriate and aggressive verbal remarks became more verbally abusive to their caretakers. Reversal of sleep-wake cycles was also exacerbated, with an increase in nocturnal activities. One 78-year-old man who had had a stable relationship with one woman for several years suddenly began to make sexual advances to other women.

While the increased aggressiveness in demented patients could have been predicted from responses in this population to other dopaminergic agents, the dose-related hypomania in otherwise healthy young women was unexpected. The hypomania may well be due to the L-amphetamine and L-methamphetamine metabolites of selegiline. Although the L-isomers are far less potent than the D-isomers, it is possible that these women had greater synthesis or decreased clearance of these metabolites so that effective blood levels were reached on a standard dose of 10 mg/d of selegiline.

We have revised our prescribing practice to employ gradual upward titration of the dose, from 2.5 mg/d to 10 mg/d over 10 to 15 days, in all patients. If patients experience significant potentiation of dopaminergic effects or signs of hypomania at a dose lower than 10 mg/d, the dose is not increased further. We no longer prescribe selegiline for significantly demented patients, and prescribe this with caution in patients with a history of cyclothymia.

The Epidemiology of Parkinson's Disease

A Case-Control Study of Young-Onset and Old-Onset Patients

• While the cause of Parkinson's disease (PD) remains unknown, recent evidence suggests that certain external factors, ie, environmental agents, may act as neurotoxins, initiating the chain of oxidative reactions that ultimately destroy neurons in the substantia nigra. Young-onset PD might result from greater exposure to a putative neurotoxin. This hypothesis has rekindled interest in the epidemiology of PD. We therefore conducted a detailed analysis of various environmental exposures and early life experiences in 80 patients with old-onset PD (at an age older than 60 years), 69 young-onset patients (younger than 40 years), and 149 age- and sex-matched control subjects. Contrary to previous reports, we were unable to implicate well water or exposure to herbicides, pesticides, or industrial toxins as significant PD risk factors. A residential history of rural living was reported by more patient cases than control subjects and was marginally significant. On the other hand, at least one episode of head trauma "severe enough to cause vertigo, dizziness, blurred or double vision, seizures or convulsions, transient memory loss, personality changes, or paralysis" occurred significantly more often prior to disease onset in patients with both young-onset and old-onset PD than in control subjects (odds ratio = 2.7). When adjusted for head trauma and rural living, smoking was inversely associated with PD, as has been previously reported (odds ratio = 0.5). There were no significant differences in early life experiences or environmental exposures between young-onset and old-onset patients. We suggest that the risk of developing PD is influenced by a variety of factors. While we were unable to link specific environmental agents with PD, our study suggests that head trauma should be reassessed as a potential risk factor for PD.

(*Arch Neurol.* 1991;48:903-907)

The cause of Parkinson's disease (PD) remains a mystery, yet accumulating evidence suggests that the interactions between environmental factors and age may underlie the pathogenesis of PD.[1,2] Moreover, the discovery of a parkinsonian syndrome induced by the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)[3,4] lends further credence to the notion that an external agent (ie, toxin) can trigger the chain of metabolic reactions culminating in the death of neurons in the substantia nigra and clinical parkinsonism ("the environmental hypothesis"). This hypothesis has stimulated the evolution of prophylactic therapies to slow PD progression[5] and provided the scientific rationale to pursue epidemiologic studies in an attempt to identify potential PD risk factors. Both descriptive epidemiological surveys of PD as well as case studies have implicated well water use, rural living, pesticide and herbicide exposure, and proximity to industry as risk factors for PD.[6-8] Several investigators have noted that exposure to environmental risk factors has been more pronounced in patients with an early onset of PD[9-11] and suggested that there may be a dose-response relationship between environmental exposure and age at PD onset. Despite these observations, an environmental toxin capable of producing PD in animals or humans has never been identified, nor have epidemics of PD been reported, as might be expected if PD were the consequence of exposure to an as yet unidentified neurotoxin. We, therefore, conducted a case-control study to further characterize the epidemiology of PD by analyzing the demographic, environmental, and early life experiences of young-onset PD patients (younger than 40 years), old-onset patients (older than 60 years), and a group of age- and sex-matched control subjects.

PATIENTS, SUBJECTS, AND METHODS

Case patients were 161 individuals with PD seen at the Graduate Hospital Department of Neurology, Philadelphia, Pa, and the Department of Neurology of the University of Medicine and Dentistry of New Jersey, New Brunswick. Patients were separated into two groups based on the age at which they experienced their first symptoms: onset before age 40 years (young-onset patients) and onset during or after age 60 years (old-onset patients). The office charts of these patients were examined to exclude individuals with a diagnosis other than idiopathic PD, who were unresponsive to antiparkinsonian medication, or who had been treated with neuroleptic drugs prior to the development of parkinsonism. Patients with significant cognitive impairment were also ex-

cluded. All eligible young-onset patients from both institutions were contacted for interviews. Old-onset patients were randomly chosen from the Graduate Hospital population.

Control subjects matched for age (within 6 years), sex, race, and participating center were selected for 149 case patients. Each case patient was asked to nominate three nonparkinsonian subjects of the same sex and race and of similar age to serve as control subjects. Relatives and spouses were not eligible to become control subjects. One control subject was randomly selected from among the individuals nominated by each case patient and was contacted for an interview. When control subjects nominated by case patients failed to meet criteria for the study and when case patients refused to nominate control subjects, the latter were selected from among patients and hospital volunteers at the Graduate Hospital. These clinic control subjects met the same criteria for eligibility as peer-nominated control subjects, and they had no history of a movement disorder.

Data regarding environmental exposures and life experiences were collected using a structured interview. Information describing lifetime residential histories included water supply and estimates of population density. Exposure to well water and rural living were evaluated as risk factors for Parkinson's disease in two ways. A person was considered exposed to these environments if the residential history recorded at least 1 year of residence where the water source was identified as "private well or spring" and "rural" by self-report. Additionally, the cumulative number of years of residence in communities specified in this way was calculated. Exposure to insecticides and herbicides was measured by self-report. Individual questions were asked regarding use of the agents within the home, in the yard or garden, and in the neighborhood, either by members of the household or by professionals. Summary variables indicate exposure either to pesticides or herbicides if any exposure was reported. Head trauma, severe enough to cause vertigo or dizziness, loss of consciousness, blurred or double vision, seizures or convulsions, memory problems, personality changes, or paralysis, was considered a head injury for purposes of this study. Detailed smoking histories were recorded, and a smoker was considered anyone who smoked at least 1 cigarette per week for a year or more.

The strength of the association of environmental exposures with PD was assessed by computation of odds ratios (OR) or as an estimate of relative risk. Statistical methods appropriate for the analysis of matched-pair data were used to calculate odds ratios, confidence intervals (CI), and tests of statistical significance.[12] For ease of interpretation, percentages of case patients and control subjects who were exposed to environmental risk factors are reported without regard for matching; however, all analyses were performed on matched pairs. Confounding variables were evaluated by the conditional logistic regression model.[13] This model was used to adjust for the influence that these variables might have on each effect of interest. Odds ratios were also computed separately within younger and older matched pairs to examine whether the pattern of risk was similar in these two groups. This pattern was also formally tested using the logistic regression model. Finally, odds ratios for differing levels of exposure were tested for dose-response trends by logistic regression.

RESULTS

The 149 matched pairs comprised 69 young-onset and 80 old-onset pairs. Of the young-onset control subjects, 40 (58%) were peer nominated and 29 (42%) were selected from the two medical centers. Twenty-three old-onset control subjects (29%) were peer nominated, and 57 (71%) were clinic control subjects. The mean age at onset of disease for younger case patients was 34.8 years, with a mean age at diagnosis of 37.4 years, whereas the mean age at onset for older case patients was 66.9 years, with a mean age at diagnosis of 67.6 years. Overall, case patients participating in this study had been treated for an average of 8.2 years (SD = 6.4). Ninety-six percent of the study sample were white, and 60.4% were male (Table 1).

Rural living was reported more often by case patients than by control subjects, although rural residence did not achieve statistical significance (OR = 1.7, 95% CI = 1.0 to 2.9). This estimate did not change after adjustment for a history of smoking and prior head injury (Table 2); it increased only slightly with adjustment for smoking, head injury, and well water exposure (OR = 1.8, 95% CI = 1.0 to 3.4), but was not statistically significant at the .05 level. Exposure to well water for 1 year or longer was reported equally by case patients and control subjects (Table 2), and it did not change appreciably after adjustment.

Insecticide and herbicide exposure showed no significant association with PD (Table 2). Eighty-seven percent of case patients and 91.3% of control subjects reported exposure to insecticides, and odds ratios with and without adjustment were not statistically significant. The prevalence of herbicide exposure

was lower than that of insecticides, with 54% of case patients and 52% of control subjects reporting herbicide use in lawn, garden, or neighborhood. Odds ratios for herbicide exposure were not significant, and adjustment did not appreciably alter the estimate.

Other variables considered included education, smoking, and head injury (Table 2). Twelve years or less of school, including vocational training, was reported somewhat more often by case patients than by control subjects, but the difference was not statistically significant. Smoking was less common among case patients than it was among control subjects, with an OR of 0.6 and 95% CI from 0.4 to 1.0. Adjustment did not influence the association between smoking and PD. An episode of head trauma was associated with PD. The unadjusted OR for any prior head injury compared with no head trauma was 2.7 (95% CI, 1.4 to 5.2). After adjustment, the association between head injury and PD remained highly significant, with an OR = 2.9 (95% CI, 1.5 to 5.8).

The average number of years between the age at the time of most recent head injury and age at PD onset was 19.8 years. An average of 20.7 years elapsed between the age at the time of most recent head injury and age at time of PD diagnosis. After adjusting for potential differences in the number of years at risk for case patients and control subjects, we calculated that an average of 25.0 years elapsed between the age at the time of most recent head injury for control subjects and the age at which their matched case patients developed PD symptoms.

There were no significant differences in the relationships between environmental risk factors and PD when comparing younger and older matched pairs (Table 3). Although the OR for rural living was 2.4 in older pairs and 1.2 in younger pairs, these two were not significantly different from each other. Head injury was somewhat more strongly associated with PD in younger pairs than in older; however, the difference between the two was not significant. Exposure to well water, insecticide, or herbicide; smoking history; or education of 12 years or less was not significant in any subgroup, nor were these ORs different from each other in young and old pairs.

There was no consistent pattern to cumulative measures of exposure and PD, although the trend was statistically significant for increasing risk with increasing numbers of head injuries (Table 4). Head injury as a risk factor was significantly elevated with one injury (OR = 2.7), but not more than one (OR = 1.3). However, the trend was significant ($P = .006$), and there was no statistical evidence of deviation from linearity. The OR for rural living was significant for 1 to 10 years of rural residence (OR = 2.5) only, and the test for trend was not significant. There was no evidence of a dose-response relationship with increasing levels of exposure to well water.

Table 3.—Odds Ratios Within Young-Onset and Old-Onset Matched Pairs*

	Young-Onset		Old-Onset		
Variable	Odds Ratio	95% CI	Odds Ratio	95% CI	Difference
Well water, ≥1 y vs never	0.9	(0.4, 2.1)	1.2	(0.6, 2.7)	NS

COMMENT

Environmental Risk Factors

In the present study, environmental risk factors were not associated with either young-onset or old-onset PD, although a history of rural living approached statistical significance. These findings differ from several prior studies linking PD to environmental risk factors. Barbeau and colleagues[14,15] found an increased prevalence of PD in proximity to lumber mills and vegetable farming regions. They proposed that agricultural chemicals were causally linked to PD. Lux and Kurtzke[16] noted a north-south gradient for PD in the United States and suggested that PD prevalence increases in the more industrialized northern regions. In their case-control study of PD in China, Tanner and coworkers[17] found PD to be associated with exposure to industrial chemicals, although China is more recently industrialized and exposure occurred after 1960 in most cases. In a study of nursing home residents in two Hong Kong districts, Ho et al[18] found PD to be associated with rural living, although a significant association required more than 40 years of exposure or greater than 20 years of farming. Koller and colleagues[6] also cited rural living as a risk factor for PD in their case-control study. The modest statistical difference between rural living in Koller's survey and the present study might result from our patient population that was recruited from largely urban referral centers. Exposure to herbicides and pesticides has also been cited as a risk factor for PD.[18-20] Furthermore, several studies have noted a greater exposure to rural living and well water in young-onset patients and suggested a dose-response relationship between environmental risk factors and age at PD onset.[9-11] Rajput et al,[10] however, were unable to identify a specific well-water contaminant in their study of PD in Saskatchewan. Moreover, most of the above surveys were done in primarily agricultural areas where exposure to agricultural chemicals is common.

Meador and colleagues,[21] on the other hand, studied death records in Georgia between 1979 and 1983 and noted no difference in PD prevalence between rural and urban living. Bharucha and others[22] failed to identify environmental risk factors in monozygotic twins discordant for PD, and Wong et al,[23] in their study of PD sibships, found no increase in herbicide or pesticide exposure in affected individuals. In their recent study, Koller et al[6] failed to detect a difference in herbicide, pesticide, or farming exposure between case patients and control subjects, despite the higher incidence of rural living in PD patients. Similarly, our study failed to detect significant environmental risk factors in either old-onset or young-onset PD. We found no dose-response relationships between environmental exposures and PD.

While a history of rural living has been a consistent theme in epidemiologic studies of PD, there is no known environmental toxin that accounts for a substantially increased risk for developing PD. Studies of PD brains have shown that neuronal loss is an active, ongoing process.[24,25] The observation that many patients are no longer exposed to putative environmental risk factors at the time of death suggests that an environmental factor responsible for PD would merely serve as a trigger, initiating the chain of metabolic reactions culminating in nigral cell death. Because dopamine cell loss likely begins 20 to 30 years prior to the onset of clinical manifestations,[25,26] one might suspect that patients with young-onset PD would have had a relatively early, brief exposure to the putative factor before disease onset. An alternative explanation is that massive exposure to a presumed environmental toxin with more rapid degeneration of dopamine neurons is responsible for young-onset PD. However, there is no evidence that young-onset PD differs from old-onset PD in its primary clinical manifestations or histopathologic findings.[27] It is, therefore, improbable that dose or duration of exposure to an environmental agent is directly related to the onset of PD. We suggest that understanding differences in inherent predisposition to PD will ultimately distinguish between young- and old-onset disease and more precisely define the role of environment.

Smoking

Smoking has been inversely associated with PD in numerous surveys (see review by Baron[28]). Our study also detected a lower incidence of smoking prior to disease onset in both young-onset and old-onset patients that was statistically significant when adjusted for head trauma. Several hypotheses have been suggested to explain the possible "protective effect" of smoking in PD, although a cogent, scientific explanation is still lacking. The physiologic effects of nicotine and cigarette smoke have been studied extensively. Nicotine promotes central dopamine transmission[29,30] and increases firing rates of nigral neurons.[31,32] Components of cigarette smoke have been hypothesized to induce cytochrome oxygenases[8] and neutralize the effects of free radicals generated from dopamine metabolism.[33] It has also been suggested that cigarette smoke contains substances that might compete with an exogenous compound for brain monoamine oxidase.[34] Smoking might, therefore, be a form of protection from exogenous or endogenous oxidative stress.[1]

While these are attractive possibilities, there remain problematic inconsistencies. In a study of the dose-response relationship between intensity of smoking and PD, Golbe and coworkers[35] failed to detect a correlation between any measure of smoking and PD severity. They concluded that smoking is probably not of benefit in preventing, delaying, or improving PD. Furthermore, Tanner and colleagues[17] failed to find an inverse association between smoking and PD in their survey of patients in China. They suggested that cultural differences in the role of smoking may be more important than any specific physiologic effect. Finally, Rajput et al[36] were also unable to confirm an inverse relationship between smoking and PD in their epidemiologic survey, but they did note a preclinical personality type more prone to "psychoneurosis and psychosomatic illness" in their patients with PD compared with control subjects. Some investigators have suggested that the decreased prevalence of smoking in patients with PD may, therefore, reflect a premorbid personality type, less inclined to become a habitual smoker.[35,36] Studying the effect of cigarette smoke on animal models of PD and understanding the pathophysiology of human disease will ultimately determine whether or not components of cigarette smoke have a significant physiologic effect that can explain the inconsistent epidemiologic observations.

Head Trauma

The most significant finding in our study was the high incidence of head trauma in patients with PD prior to the onset of disease. The relationship between head trauma and PD has been controversial since Parkinson's initial description of PD and his hypothesis that symptoms evolved following cervical trauma.[37] At present, there is no evidence that head trauma causes PD with Lewy body pathology (see review by Factor et al[38]). However, head trauma has been linked to PD in some epidemiologic studies[39] and, in their review of posttraumatic movement disorders, Koller and colleagues[40] suggest that "trauma can probably worsen Parkinson's disease or perhaps even make a latent process apparent." They included peripheral trauma and head trauma in their review. Factor and Weiner[41] found a greater incidence of head trauma with loss of consciousness in a group of patients with PD than in matched control subjects. They questioned the significance of their findings because of the long latency between the traumatic event and disease onset, despite compelling evidence that the pathologic process in PD begins many years prior to the onset of clinical symptoms.[25,26] We also detected a long latency between head trauma and the onset of PD.

Depigmentation of substantia nigra neurons with cell loss and neurofibrillary tangles are seen in the brains of boxers with parkinsonian features during life.[42] Furthermore, head trauma has been associated with other neurodegenerative disorders, including Alzheimer's disease[43,44] and amyotrophic lateral sclerosis.[45,46] Pathologic changes resembling Alzheimer's disease were recently detected in the brains of boxers with dementia.[47] Additionally, Rudelli and colleagues[48] described patients with a dementia secondary to head injury that was neuropathologically identical to Alzheimer's disease. These observations suggest that head injury may not only be a significant risk factor for Alzheimer's disease but that head trauma may also cause a spectrum of neuropathological changes that can evolve many years after the traumatic event(s). While our data do not suggest that an episode of significant head trauma causes Lewy body PD, they do suggest that the pathophysiologic sequelae of head trauma should be further studied. Head trauma may be one of many risk factors that combine in a predisposed individual to induce the complex and, as yet unknown, cascade of chemical and metabolic events that eventually cause nigral cell death and PD.

There are several limitations to our study. First, our study considered patients in whom the diagnosis of PD was not newly established, and risk factors identified in studies of prevalent cases may be influenced by differences in survival of subgroups with PD. However, this type of bias tends to underestimate risk factors that carry a poor prognosis and is unlikely to substantially influence the exposures measured here. Second, we measured exposure histories by self-report using a structured questionnaire, which raises the possibility of recall bias. If patients with PD are more likely to remember an exposure than are control subjects, the measured relative risk would be spuriously high. However, the long latency between head trauma and the onset of PD in case patients and the equivalent estimate for control subjects does not suggest any important differences in the recall of significant head trauma by time frame. Furthermore, we attempted to guard against this type of bias by asking questions regarding specific memorable exposures (eg, head trauma associated with "loss of consciousness") and by asking multiple questions regarding individual exposures (eg, herbicide and insecticide exposure).

This study was supported, in part, by an educational grant from Dupont Pharmaceuticals, Wilmington, Del.

Clinical and Genetic Analysis of Progressive Dystonia With Diurnal Variation

John K. Fink, MD; Paula D. Ravin, MD; Michelle Filling-Katz, MD; Charles E. Argoff, MD; Mark Hallett, MD

• **We examined 17 patients with progressive dystonia with diurnal variation, a dominantly inherited, generalized dystonia that begins in childhood. Dystonia was typically least severe in the morning, increased as the day continued, and markedly improved with low doses of carbidopa-levodopa. We also studied the patient's parents, children, and siblings from seven families. We observed a spectrum of neurologic involvement, phenotypic variability among siblings, and incomplete genetic penetrance. Progression of motor impairment over several years, which reaches a plateau during late adolescence, is useful in distinguishing progressive dystonia with diurnal variation from cerebral palsy and degenerative disorders. It is important to recognize the subtle, as well the extreme, manifestations of progressive dystonia with diurnal variation because it is treatable. Genetic counseling must consider that mildly affected parents with little or no disability may have profoundly affected children. Appreciation of the phenotypic variability and degree of genetic penetrance will permit detailed genetic and biochemical analyses.**

(*Arch Neurol.* 1991;48:908-911)

Progressive dystonia with diurnal variation (PDDV) (Segawa's dystonia)[1] is a dominantly inherited, generalized dystonia[2] that begins in childhood, usually fluctuates during the day, and dramatically improves with low doses of carbidopa-levodopa. Because of inadequate recognition, this treatable condition may be misdiagnosed as cerebral palsy, familial spastic paraparesis, or psychogenic disturbance. Without treatment, PDDV may be disabling. We analyzed the clinical course of 17 patients with PDDV, as well as their parents, children, and siblings from seven families to appreciate the clinical spectrum of this disorder.

PATIENTS AND METHODS

We studied 17 patients (five male and 12 female) with PDDV and their parents, progeny, and unaffected siblings between July 1984 and December 1989. Informed consent was obtained from the adult subjects and the parents of minor patients. We made the initial diagnosis of PDDV in 12 patients. In five patients diagnosis was established previously. Patients' ages ranged from 4 to 45 years at the time of our initial examination. Progressive dystonia with diurnal variation was diagnosed on the basis of primary, generalized dystonia that began in childhood, exhibited diurnal fluctuations, and improved with low doses of carbidopa-levodopa. The criterion of diurnal fluctuations was not used in three patients whose first-degree relatives had typical fluctuations. Two mildly affected patients are untreated and one patient is treated with trihexiphenidyl. The diagnosis of PDDV in patient 6, who died before our evaluation, was made after we examined and treated similarly affected siblings and reviewed his medical records and videotape recordings. One patient, who was previously evaluated at the National Institutes of Health, Bethesda, Md, was interviewed by telephone, but was not reexamined.

RESULTS

Laboratory Findings

The results of routine laboratory tests on 14 patients, incuding complete blood cell count, serum copper, ceruloplasmin, amino acid analysis, and electrolytes, were normal. Cranial magnetic resonance imaging and/or computed tomographic scans (in 14 patients) were normal. Reduced concentrations of homovanillic acid and biopterin in cerebrospinal fluid (in patients 4, 5, 10, and 11)[3] and tetrahydrobiopterin (BH_4) administration (in patients 4, 5, 10, 13, and 14 through 15)[4,5] have been reported previously.

Onset, Progression, and Distribution of Dystonia

The clinical characteristics of our patients with PDDV are summarized in

Family-Patient No.	Age, y†/Sex	Age at Onset, y	Dystonia Progression (Age, y‡)
I-1	45/F	8	Yes (8-14)
I-2	27/F	12	No
I-3	11/M	1.5	Yes (1.5-2)
I-4	8/M	1.5	Yes (1.5-3)
I-5	11/M	1	Yes (1-2)
II-6	12/F	2	Yes (5-11)§
III-7	7/F	5	Yes (5-7)§

the Table. Prenatal and perinatal periods and early developmental milestones were normal in all patients. Difficulty walking due to pes equinovarus, noted at 1.5 to 11 years of age (mean age, 6 years), was the initial symptom in each patient. In the majority of patients, dystonia began as a progressively worsening condition. In three patients (patients 6, 10, and 11), however, worsening of symptoms did not begin until several years after the initial appearance of dystonia. The period of progression lasted 3 to 11 years (mean, 7 years). Dystonia remained relatively constant thereafter. None of seven adults had worsening of dystonia after age 15 years. Thus far, dystonia has been nonprogressive in one mildly affected child and one adult (ages 5 and 27 years, respectively). In 15 patients, however, dystonia increased in the initially affected region and spread to the contralateral lower extremity, pelvis (11 patients), trunk (seven patients), upper extremities (12 patients), and neck (10 patients). Jaw and facial involvement (six patients) was generally asymptomatic (five patients). Speech and swallowing were involved in two brothers. The natural history of the disorder was partially obscured in four children because carbidopa-levodopa was prescribed before progression had spontaneously abated.

Neurologic deficits were limited to pyramidal and extrapyramidal systems. On examination, dystonia was generalized, affected the lower extremities most severely, and increased with action in all patients. It was symmetric in three patients and asymmetric in 14 patients, with moderate to marked asymmetry in seven of them. At least mild corticospinal tract dysfunction (velocity-dependent spasticity and hyperreflexia) was present in 12 of 16 patients examined. In six patients, spasticity was moderate to marked and equaled the degree of dystonia. Extensor plantar responses (11 patients) often disappeared with carbidopa-levodopa therapy (at least five patients). Myoclonic dystonia was present in two brothers.

Diurnal Fluctuation

Fourteen patients had diurnal fluctuation of motor performance due to increased dystonia and spasticity. These fluctuations differed from gradual, fatigue-related worsening seen in many disorders, because symptoms worsened at approximately the same time each day. Fluctuations were of variable intensity, sometimes representing the difference between ambulation and nonambulation (four patients). The fluctuation rate also varied. In 10 patients, improved motor function lasted 1 to 4 hours after awakening and reached a nadir around 10 AM to 12:00 noon. In four patients, however, it lasted only 30 to 45 minutes after awakening each morning, and two of these patients were ambulatory only during this interval. Improvement following an afternoon nap was typical, but not as pronounced as that seen in the morning. Diurnal fluctuations were absent in three mildly affected patients whose severely affected siblings (of one patient) or parents (of two patients) had typical diurnal fluctuations.

Therapy

Fourteen patients were treated with levodopa (0.7 to 2.9 mg/kg per day) and carbidopa (0.2 to 0.7 mg/kg per day) and have experienced marked clinical improvement. There has been no appearance of tolerance in 6 months to 13 years (mean, 5 years) of treatment. One patient, unable to tolerate carbidopa-levodopa because of nausea, has benefited from trihexyphenidyl (10 to 50 mg/d) for more than 10 years. Two mildly affected patients (patient 2, age 27 years, and patient 10, age 5 years) are currently untreated.

Adverse effects of carbidopa-levodopa therapy were frequent and included nausea (11 patients); choreoathetosis (three patients); behavorial hyperactivity and attention deficit disorder (two patients); insomnia, paranoia, and depression (one patient); and hypomania (one patient). These side effects were reversible with dosage reduction.

Genetic Analysis

The families were of nonconsanguineous, non-Jewish, northern European ancestry (Swedish/Norwegian, German/Norwegian, English/Irish, English-French/German, American Indian-Irish/Swedish-Polish, English-Irish/Norwegian, English/English-Dutch).

The pedigrees of these families are shown in the Figure. We examined 17 of 20 parents and obtained information

At Risk: Normal Examination but Younger Than the Age at Disease Onset in Family Members
Miscarriage

Pedigree analysis of progressive dystonia with diurnal variation (PDDV).

about unavailable (one) and deceased (two) parents. Four of the 20 parents (20%), all women, had extrapyramidal disturbance, including typical PDDV (two parents), blepharospasm and oral-facial dyskinesia (one parent), and torticollis and blepharospasm (one parent). Two parents were more severely affected (moderate to marked disability) than were their children (no disability or mild disability). Two parents had only mild symptoms (no disability) yet had children with marked dystonia, requring wheelchair use.

Five individuals (all women) with PDDV or mild disturbance of the extrapyramidal system had a total of 15 children, of which eight (53%) had PDDV. Although neurologically normal, several children (less than 5 years of age) are considered at risk for developing PDDV, because they are younger than the presenting age of their family members. Spontaneous abortion was reported by only one patient.

The patients' siblings (13 full and four half siblings) were evaluated by physical examination (16 siblings) or telephone contact (one sibling) and found to be unaffected. Thus, 17 (50%) of 34 siblings (full and half) had PDDV. Although involvement among siblings was generally similar, there was marked heterogeneity in one family—patient 8 had severe dystonia and was not ambulatory while his brother (patient 9) had only mild foot dystonia that did not require treatment.

COMMENT

Progressive dystonia with diurnal duration is an important and treatable disorder that should be considered in children and adults presenting with gait disturbance. It is readily diagnosable in patients with childhood-onset dystonia that fluctuates during the day and progresses over several years, particularly when there are similarly affected family members. Clinical suspicion and a trial of carbidopa-levodopa should not depend on a typical family history and diurnal fluctuations, however. There may not be similarly affected family members because of incomplete genetic penetrance and phenotypic variability. Diurnal fluctuations may be subtle, absent, or unrecognized if they occur rapidly or early in the morning. Progressive dystonia with diurnal duration should also be considered in patients with marked, generalized spasticity and only mild dystonia. It is essential to ask about similarly or even subtly affected family members and whether motor performance is significantly better (even for only 30 to 60 minutes) early in the morning or following an afternoon nap. Demonstration of reduced biopterin concentration in cerebrospinal fluid, although useful in confirming the clinical diagnosis, is not specific for PDDV. Decreased BH^4 has been reported[6] in Parkinson's disease, Shy-Drager's syndrome, and Steele-Richardson-Olszewski syndrome and might be expected in other degenerative conditions associated with a decreased number of BH^4-containing catecholamine or serotonin neurons.

The absence of cognitive impairment (Hallervorden-Spatz disease),[7] organomegaly and vertical gaze disturbance (Niemann-Pick disease type C),[8] aminoaciduria (biopterin synthetase deficiency[9] and glutaric acidemia[7]), and Kayser-Fleisher rings (Wilson's disease) helps exclude degenerative conditions associated with dystonia. Pigmentary retinopathy, similar to that occurring in neuronal ceroid lipofuscinosis, has been reported in a family with PDDV.[10] Onset of dystonia (particularly focal dystonia) in adulthood[11] and continued progression in the third decade of life are more consistent with dominantly inherited or idiopathic torsion dystonia than with PDDV. However, only the response to carbidopa-levodopa can reliably distinguish these types of dystonia.

Pyramidal tract disturbance is common, may be prominent (six of our patients), and often leads to erroneous diagnoses of familial spastic paraparesis and cerebral palsy.[12,13] Normal developmental milestones, onset of symptoms after infancy, and progression of symptoms over several years distinguish PDDV from cerebral palsy. Lack of progression beyond adolescence and absence of bladder and bowel involvement distinguish PDDV from familial spastic paraparesis.

Progressive dystonia with diurnal variation is often misdiagnosed in patients and its symptoms are ascribed an emotional basis. This occurred in nearly half of our patients. This misdiagnosis may be particularly common when a child can freely walk to school or during an early morning visit to the physician's office, but is unable to walk later in the day. Psychogenic movement disorder should remain a diagnosis of exclusion and should not be considered until after a trial of carbidopa-levodopa.

Carbidopa-levodopa therapy provides rapid and sustained clinical improvement. Although clinical response is obvious within 24 to 48 hours, maximum benefit, requiring dosage optimization and physical therapy, may require 8 weeks or longer. We use the following diagnostic trial: carbidopa-levodopa (Sinemet 25/100) is initiated as a half tablet each day for 2 days and then increased to 1.5 to 2 tablets each day (in two to three divided doses) over 7 to 10 days; this dosage is maintained for 7 days, and if there is no improvement, discontinued over 7 days. Administration of carbidopa-levodopa in a double-blind, placebo-crossover manner may be useful for selected, consenting patients. Dose-related side effects are frequent, particularly when beginning therapy. Carbidopa-levodopa treatment may be delayed until adulthood and still provide long-lasting benefit. Patients unable to tolerate carbidopa-levodopa have benefited from trihexyphenidyl.

Pedigree analysis (Figure) in our patients suggests dominant mendelian inheritance because the incidence of dystonia in the children of affected parents was approximately 50%. Pseudodominant inheritance cannot be excluded, however. The high female-to-male ratio (11:6) raises possibilities of reduced viability of affected male fetuses, X-linked inheritance, sex-influenced expression, or ascertainment bias. There was no evidence of reduced fertility or frequent miscarriages to suggest reduced fetal viability. Although X-linked inheritance in our families cannot be excluded, two previous reports[1,14] have each had evidence of male-to-male transmission. If the disorder in our patients is identical to that in these other families, and not a highly similar phenocopy, it is likely that expression of PDDV is sex influenced.

Ascertainment bias could also contribute to the high female-to-male ratio. There was a trend in our study for male individuals to be affected earlier and more severely than female individuals. This was particularly true with respect to pyramidal tract disturbance. It is possible that male patients are more frequently diagnosed as having severe cerebral palsy, while female patients may remain sufficiently ambulatory to have dystonia accurately recognized.

The occurrence of spontaneous mutations and nonpaternity must be considered when estimating genetic penetrance. Spontaneous mutation cannot be excluded in families III, VII, and—possibly—II, in which neither parent is affected and in which only one child has PDDV. Nonpaternity (and possibly autosomal recessive inheritance) cannot be excluded in family IV. Among families with evidence of genetic transmission (either parents and children affected or more than one affected child per family), three (of seven) sets of parents had no evidence of extrapyramidal dysfunction. Disease penetrance is thus incomplete and estimated to be 4/7 or 57%.

Marked phenotypic variability within and between families was noted with respect to the occurrence, rate, and magnitude of diurnal fluctuations, the degree of dystonia (which varied from no disability to profound impairment), and involvement of oral-pharyngeal musculature. In general, diurnal fluctuations were less apparent in those with only mild dystonia as well as in three profoundly affected children, who only had brief periods of improved motor function each morning. The genetic and biochemical basis for phenotypic variability is not known. Clinical heterogeneity within a family is presumably related to the presence of modifying genes, whose expression ameliorates or exacerbates the tendency for dystonia. Heterogeneity between families may be related to the effect of different mutations affecting the same gene. On the other hand, we cannot exclude the possibility that different families represent phenotypically similar disorders due to mutations of different genes.

The biochemical basis of this disorder is not known. Although marked levodopa responsiveness suggests a deficiency of dopamine or dopaminergic neurons, it is also possible that levodopa compensates for another neurotransmitter disturbance. Whether BH_4 deficiency reflects decreased BH_4 synthesis, increased BH_4 catabolism, or fewer BH_4-containing neurons[15] (catecholaminergic and serotonergic) is not clear. The physiologic basis for greater occurrence (and/or greater recognition) of this disorder in female individuals is also not known. Understanding the clinical spectrum of this disorder is a prerequisite for detailed genetic and neurochemical analyses. Moreover, appreciation of the subtle and extreme manifestations of this disorder will lead to greater recognition of treatable patients.

We thank B. J. Hessie for editorial assistance, Lynette Girbach for expert secretarial assistance, Brian Vlcek, MD, for patient referral, and Roscoe Brady, MD, for his support of this investigation.

This manuscript is dedicated to the memory of Dr M. R. Filling-Katz.

Abnormalities of Cutaneous Blood Flow Regulation in Patients With Reflex Sympathetic Dystrophy as Measured by Laser Doppler Fluxmetry

Mark D. Bej, MD, Robert J. Schwartzman, MD

• The response of cutaneous blood flow to autonomic stimuli was evaluated in eight patients with clinically staged reflex sympathetic dystrophy and eight healthy control subjects. Blood flow was measured in the affected and contralateral extremities by laser Doppler fluxmetry. Five autonomic stimuli were applied to the contralateral extremity during blood flow measurement in the ipsilateral affected extremity. Affected limbs of patients with reflex sympathetic dystrophy were found to have statistically significantly increased blood flow during the Valsalva maneuver and cold pressor test, while blood flow decreased in normal controls. No significant differences were found in limb temperature or baseline blood flow between patients and controls. Reflex sympathetic dystrophy stage did not affect response to the procedures. Control subjects demonstrated a rhythmic cycling of cutaneous blood flow that was absent in patients with reflex sympathetic dystrophy. These results support a central abnormality of the sympathetic nervous system in reflex sympathetic dystrophy.

(*Arch Neurol.* 1991;48:912-915)

Reflex sympathetic dystrophy (RSD) is a symptom complex characterized by pain, hyperesthesia, vasomotor instability, temperature changes, and subsequent dystrophy of the affected body part. The condition was first described by Mitchell[1-3] in 1864 and has been divided into stages.[4] Stage I (acute) consists of burning or aching pain, hyperalgesia, edema, dysthermia, and increased hair and nail growth. Stage II (dystrophic) consists of brawny edema, hyperhidrosis, livedo reticularis, cyanosis, hair loss, and hypothermia. In Stage III (atrophic) disease, the pain spreads proximally, the skin thins, vasomotor instability is prominent, fascia thickens, contractures occur, and there is atrophy of all affected tissues. Initiation of RSD is generally secondary to trauma, but many other precipitating factors have been identified.[4] Progression by stages is variable, and occasionally the condition may resolve spontaneously.[4]

Multiple theories regarding the pathogenesis of RSD have been advanced.[5-11] Due to the characteristic mottling, edema, and vasomotor changes, RSD has long been considered a manifestation of sympathetic nervous system dysfunction.[12] In support of this theory, sympathetic ganglionic blockade or sympathectomy frequently alleviates the pain and symptoms of stage I disease.[13]

The purpose of our study was to measure the cutaneous blood flow in the affected and contralateral extremities of patients with RSD in response to various maneuvers that influence autonomic tone to understand further the autonomic physiology in patients with RSD.

PATIENTS AND METHODS

The most affected extremity and the contralateral extremity (either affected or unaffected) of eight patients with various stages of RSD were studied (Table 1). In all patients, disease was staged according to established criteria.[4] The patients' mean (±SD) age was 34±7 years; seven patients were women and one was a man. One arm of each of eight normal control subjects was also studied. The normal controls consisted of five women and three men with a mean age of 27±5 years. All subjects participated in the study after first providing informed consent.

Cutaneous blood flow was measured with a laser Doppler monitor (LaserFlo BPM-403-ATSI; TSI Inc, St Paul, Minn). This unit utilizes a low-power (1.6-mW) helium-neon laser, whose light is delivered to the skin surface via a flexible fiberoptic cable and is zeroed against a white surface according to manufacturer's instructions. The return signal is converted to a measurement of blood flow, volume, or velocity in the epidermal capillary loops,[14] according to a model developed by Bonner et al.[15] The monitor's analog 0- to 2.5-V output was connected through an analog/digital converter board (DT-2801; Data Translation, Marlboro, Mass) to a microcomputer (IBM-XT; International Business Machines, Boca Raton, Fla). Digital blood flow data were collected 30 times per second, averaged, and stored.

All subjects were examined after they had voided. They practiced the Valsalva maneuver and squeezing the dynamometer (Smedley-type; Therapeutic Instruments, Clinton, NJ) in several sessions preceding the experiment. A maximum strength was recorded for each hand. All patients rested in the supine position for at least 10 minutes before the initiation of studies and remained thus throughout the study. Lights were dimmed, and noise was kept to a minimum. Blood pressure, pulse, and extremity temperatures were recorded. The laser Doppler probe was placed dorsally, proximal to the web of the second and third digits, and the hand was lightly taped to the bed. A 2-minute baseline ("long-baseline") reading was recorded. In normal controls, the laser Doppler probe was placed on the nondominant hand, and all five procedures were performed with the dominant hand.

In patients with RSD, the laser Doppler probe was first placed on the most affected extremity, and the contralateral extremity was used for the procedures. The process was then reversed, with the probe on the contralateral extremity. This extremity could be symptomatic (affected) or nonsymptomatic (unaffected) due to RSD. The most affected extremity was now used for the five procedures. In the tables, affected, unaffected, and normal refer to the extremity with the probe, not the extremity undergoing the procedures.

The five procedures in the protocol were, in the order performed: (1) hyperventilation, (2) Valsalva maneuver, (3) dynamometer static grip, (4) exercise, and (5) cold pressor test. A 30- to 60-second baseline ("short-baseline") reading was obtained immediately before each procedure. Timing marks were inserted into the data stream to indicate when the patient was instructed to begin and end each procedure. Sufficient time, usually 1 to 3 minutes, was allowed between procedures for the blood flow to return to the previous short-baseline value. Each procedure is described below:

1. *Hyperventilation:* Deep breathing was coached by one of us (M.D.B.) for maximal effort and was sustained for 30 seconds.

2. *Valsalva maneuver:* The patient exhaled a full-inspiration breath through disposable positive end-expiratory pressure valves, attaining a minimum pressure of 30 cm H_2O. Before the study, each subject practiced this exhalation so that he or she just opened the valves. Exhalation continued for 30 seconds, or as limited by breath volume.

3. *Dynamometer:* This maneuver consist-

ed of maintaining static grip for 30 seconds at one half of the previously determined maximal strength of that hand.

4. *Exercise:* The extremity was fully flexed and extended, at the elbow or the knee, at a maximal rate for 30 seconds.

5. *Cold pressor test:* The extremity was inserted to the level of the wrist or ankle in water at 0°C for 30 seconds. It was then allowed to return to baseline temperature.

The percent change in cutaneous blood flow, $\Delta\%J$, was calculated for each procedure with the following formula: $\Delta\%J = (J_1 - J_0)/J_0 \times 100\%$, where J_1 is the average blood flow during the procedure, and J_0 is the average short-baseline blood flow. Percent change flow among the categories of extremities was compared with Student's *t* test, and corrected for multiple comparisons by the method of Tukey-Kramer.[16-18] Analysis of variance was used to evaluate interlimb temperature differences. A commercially available software package (SYSTAT; Systat Inc, Evanston, Ill) was used for all statistical analyses.

RESULTS

The age, sex, stage, site of maximal involvement, and precipitating insult of all patients with RSD are summarized in Table 1. Baseline blood flow, skin temperature, and percent change in blood flow with each procedure are summarized in Table 2 and Fig 1. *P* values for comparison of affected vs unaffected limbs, affected vs normal control limbs, and unaffected vs control limbs are listed in Table 3.

The *P* values were obtained from Student's *t* test corrected for multiple comparisons. Few patients with RSD were able to squeeze the dynamometer with their affected limb, resulting in an insufficient number of blood flow measurements in unaffected limbs for a *t* test to be performed on the results of this procedure. The comparison of affected and normal limbs in this protocol is thus Student's *t* test without the Tukey-Kramer correction.

Statistical significance at the $P \leq .05$ level was achieved for the comparison of affected vs normal limbs for the cold pressor test and Valsalva maneuver. In normal controls, blood flow decreased or remained essentially unchanged in the extremity opposite the one being stimulated during the procedure. In patients with RSD, however, blood flow generally increased in both affected and unaffected limbs. This was the case for stimuli acting through both central and peripheral pathways.

Table 1.—Data for Patients With Reflex Sympathetic Dystrophy Studied

Patient/Age, y/Sex	Stage	Site of Maximal Involvement	Precipitating Event
1/30/F	II	R leg	Arthroscopy
2/36/F	III	L arm	Intravenous catheter insertion
3/30/F	III	L leg	No insult known
4/49/M	II	L arm	Trauma to hand and surgery
5/29/F	II	R leg	L-5-S-1 laminectomy
6/35/F	II	R hand	Finger trauma
7/37/F	I	R arm	Motor-vehicle accident
8/28/F	III	R arm	Shoulder dislocation and repetitive movement

Table 2.—Mean ± SD Baseline Blood Flow, Skin Temperature, and Percent Change in Cutaneous Blood Flow in Affected, Unaffected, and Normal Limbs

Procedure	Affected	Unaffected	Normal
Baseline flow, mL/min per 100 g	1.0 ± 0.5	1.3 ± 0.5	2.3 ± 2.0
Skin temperature, °C	32.7 ± 3.4	32.2 ± 3.1	32.8 ± 4.4
Hyperventilation, %	+33 ± 49	+27 ± 35	+2 ± 17
Valsalva, %	+14 ± 32	+5 ± 49	−32 ± 34
Exercise, %	+85 ± 116	+91 ± 143	−5 ± 11
Cold pressor, %	+34 ± 57	+21 ± 37	−17 ± 14
Dynamometer, %	+2 ± 12	+0 ± . . .*	−4 ± 15

*Insufficient number of patients was available to complete procedure.

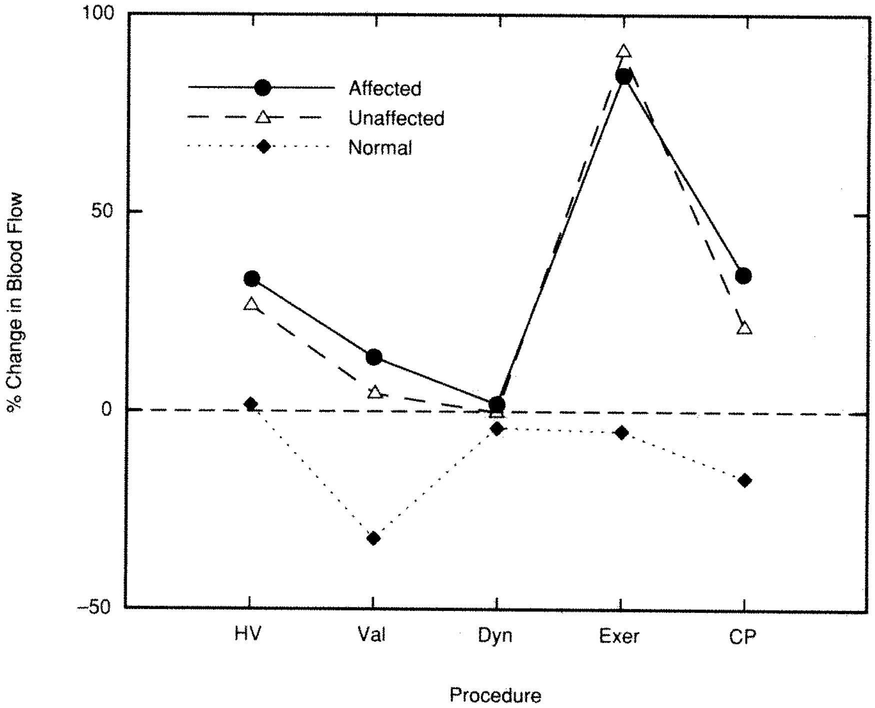

Fig 1.—Percent change in blood flow with each procedure in affected, unaffected, and normal limbs. HV indicates hyperventilation; Val, Valsalva maneuver; Dyn, dynamometer; Exer, exercise; and CP, cold pressor test.

No other comparisons were significant at this confidence level. The trend was for the unaffected limbs of patients with RSD to respond more like affected limbs rather than normal control extremities. There were no definable differences among the three groups with regard to extremity temperature ($P = .95$). Baseline cutaneous blood flow, although lower in patients with RSD, was not significantly different from that in controls ($P = .13$). Stage of RSD was not a significant factor in determining baseline blood flow ($P = .71$), response to Valsalva maneuver ($P = .98$), or response to the cold pressor test ($P = .47$).

During measurement of the short- or long-baseline blood flow, the instantaneous flow in patients with RSD in either limb was remarkably stable. In contradistinction, instantaneous blood flow of normal controls fluctuated wide-

Table 3.—Tukey-Kramer *P* Value for Pair-Wise Comparisons in Affected, Unaffected, and Normal Limbs

Procedure	Affected vs Unaffected	Affected vs Normal	Unaffected vs Normal
Initial flow	.88	.17	.36
Skin temperature	.97	.99	.93
Hyperventilation	.95	.22	.47
Valsalva	.92	.05	.19
Exercise	.99	.31	.25
Cold pressor	.86	.05	.24
Dynamometer	...*	.38†	...*

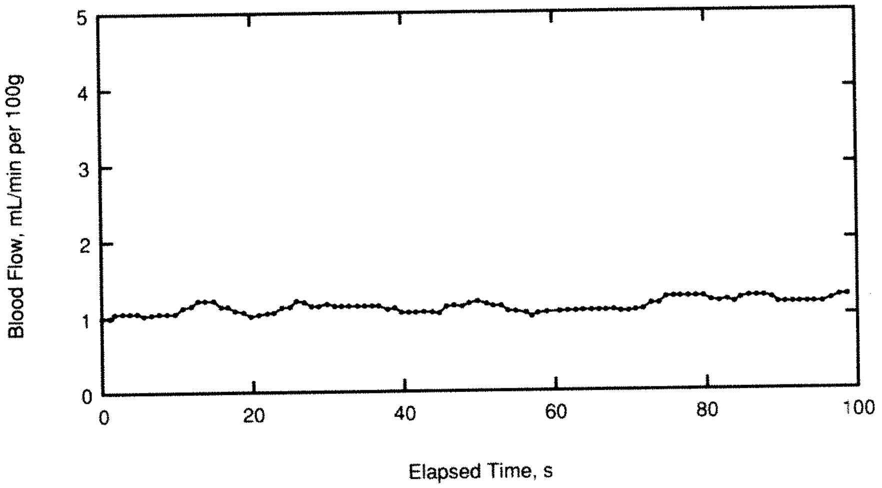

Fig 3.—Long-baseline measurement recording of blood flow over time in patient 8 with reflex sympathetic dystrophy.

ly over time in a sinusoidal pattern. As such, it was difficult to determine when rebound effects ceased and when normal-baseline blood flow began. This is best illustrated by a comparison of the long-baseline measurement of control subject 5 (Fig 2) with the long-baseline measurement of patient 8 with RSD (Fig 3).

COMMENT

Current support for the role of the sympathetic nervous system in the pathogenesis of RSD is based primarily on the relief of signs and symptoms of the disease by sympathetic denervation. In its later stages, the disease is most often sympathetically independent.[19-21] The nature of the sympathetic defect, its extent, and its sustaining mechanisms are unknown. Our study demonstrates that the defect is, at least in some aspect, central.

In our study, subjects completed five procedures that stimulate the autonomic nervous system. The Valsalva maneuver increases right atrial pressure[22] by stimulation of arterial baroreceptors and cardiac mechanoreceptors.[23] The effects of exercise and handgrip on the sympathetic system are most likely mediated by peripheral receptors in muscle.[24] Hyperventilation may also act via peripheral receptors in the muscles of respiration, but it produces a respiratory alkalosis as well, stimulating arterial chemoreceptors.[25] The cold pressor test activates sympathetic neurons in the intermediolateral column of the spinal cord.[26] Their postsynaptic sympathetic efferent fibers synapse with vasoconstrictive α and vasodilatory β_2 receptors on capacitance and resistance vessels.[27,28] Sympathetic vasodilator fibers have been identified in the forearm,[29,30] but blood flow in the hands, feet, ears, and lips has been shown to be mediated predominantly by changes in vasoconstrictor tone.[31]

Our results indicate that cutaneous blood flow responds differently to peripheral and central autonomic nervous system stimuli in patients with RSD than in normal controls. In control subjects, significant decreases in extremity blood flow were seen in the response to the Valsalva maneuver (32%) and cold pressor test (17%), which confirms the results of a prior study by Low et al.[32] Decreased blood flow in the extremities has also been described by Bannister and Mathias[33] for the Valsalva maneuver. These results also confirm those presented by Rosén et al,[34,35] who demonstrated that the cold pressor test caused a mean 37.5% blood flow decrease in controls but only a 0% to 8% drop in patients with RSD. The cold pressor and tilt tests cause an increase in plasma norepinephrine levels in normal control subjects.[36] Plasma concentration of norepinephrine under these conditions in patients with RSD is unknown.

The decreased blood flow seen during all procedures except hyperventilation suggests that blood is either pooled in the capacitance vessels of the extremity under study or is shunted to another body area. It would appear likely that exercise, handgrip, and hyperventilation would shunt blood to the exercised muscles.

The response in patients with RSD is different from that of normal controls for all five autonomic stimuli. Blood flow was invariably increased in both the affected and unaffected limbs. This finding of bilaterally increased blood flow, in conjunction with the clinical phenomenon of bilateral spread of pain, strongly suggests central involvement in RSD. A previous study demonstrated no side-to-side differences in skin temperature, blood flow, or skin conductance.[37] This can arise from a central defect that causes bilateral dysfunction of sympathetic control. We suggest that the bilateral extremity blood flow increases demonstrated in our study represent a loss of differential control of the blood supply to any one extremity, perhaps by deranged sympathetic vasoconstriction in the area of study or by abnormal sympathetic vasodilation in the resistance and capacitance vessels.[38] Under these circumstances, any central (chemoreceptive or thermoreceptive) mechanism that causes increased blood flow may well have a global effect. Our data also indicate that the "unaffected" extremity is much more likely to respond as an affected extremity, rather than as a normal control extremity.

In our study, there was no interlimb temperature difference in patients with RSD; nor was there a significant difference between these patients and controls. This is in contrast to the results of previous studies.[37] Comparison of baseline blood flow in affected, unaffected, and control limbs also reveals no statistically significant differences. This is in contrast to a study by Sylvest and others[39] in patients with RSD that demonstrated both increased resting muscle temperature and global blood flow in affected extremities. However, the "normal controls" in their study were patients with nerve injuries without clinical RSD, rather than healthy subjects. This study revealed no correlation between limb temperature and baseline cutaneous blood flow.

Vascular physiologists have long known of apparently spontaneous changes in arteriolar diameter.[40,41] These changes cause rhythmic variations in cutaneous blood flow that vary widely from individual to individual and that can be blocked by topical application of anesthetic medications.[42] Patients with RSD appear to have lost the ability to effect these variations, as evidenced by the ease in establishing a "short-baseline" readings in these patients compared with normal controls.

The effects of medications, sympathetic block, and sympathectomy were not evaluated in our study. The RSD stage was not found to significantly affect baseline blood flow or responses to the Valsalva maneuver or cold pressor test. The only newly diagnosed, untreated patient (patient 4) exhibited the most dramatic response to all stimuli. Further study of patients with each stage of RSD, before and after the performance of specific therapeutic maneuvers and the administration of medications, is needed, to differentiate the effects of therapy on central and peripheral sympathetic control of the cutaneous blood flow in patients with RSD. If a consistent pattern can be identified, a noninvasive, quantifiable test for early confirmation of RSD may be achieved.

This investigation was supported in part by grant 080-01673 from the Pfeiffer Foundation, Santa Monica, Calif.

Transient Ischemic Attacks With and Without a Relevant Infarct on Computed Tomographic Scans Cannot Be Distinguished Clinically

Peter J. Koudstaal, MD; Jan van Gijn, MD; Jan Lodder, MD; Cor W. G. M. Frenken, MD; Marinus Vermeulen, MD; Cees L. Franke, MD; Albert Hijdra, MD; Carel Bulens, MD, for the Dutch Transient Ischemic Attack Study Group

• We prospectively studied clinical and computed tomographic (CT) scan findings in 79 patients with a transient ischemic attack (TIA) and a relevant cerebral infarction on CT, also known as *cerebral infarction with transient signs* (*CITS*). We compared the results with those of 527 concurrent patients with TIA and without cerebral infarction and also with 646 patients with persistent neurological symptoms and a relevant infarct on CT. All patients were participating in a multicenter trial. In both groups, most infarcts were of the lacunar type. Compared with TIAs without cerebral infarction, patients with CITS slightly more often had a history of hypertension (52% vs 33%), the attacks lasted longer (>1 hour, 52% vs 34%) and disappeared more slowly (over the course of hours, 39% vs 24%), and the symptoms more frequently involved speech (61% vs 41%). Despite these small differences, the reverse—the prediction of evidence on CT of infarction on the basis of the nature or time course of symptoms—proved impossible, since in each category the majority of patients had a normal CT scan. In comparison with patients with stroke and visible infarction, patients with CITS slightly more often had abnormal speech (61% vs 45%) and had a larger number of attacks (multiple attacks, 46% vs 18%). In conclusion, we found only minor clinical differences between patients with TIA with or without a relevant infarct on CT and equally small differences between patients with CITS and patients with stroke and cerebral infarction. These clinical similarities do not exclude a difference in prognosis.

(*Arch Neurol.* 1991;48:916-920)

A *transient ischemic attack* (*TIA*) is defined as an acute focal neurologic deficit lasting less than 24 hours.[1] This arbitrary time limit has proved inaccurate with regard to the integrity of brain tissue, since a proportion of patients with TIAs show a relevant cerebral infarct on computed tomographic (CT) scanning.[2-6] This condition has been called *cerebral infarction with transient signs* (CITS) by Waxman and Toole.[7] These authors have speculated that patients with CITS have a different lesion in the vascular tree than do patients with TIA and without a demonstrable infarct and that their prognosis is different. Bogousslavsky and Regli[8] initially found an association between CITS and occlusion of the carotid artery, but, in a subsequent study of 57 patients with TIA, including 16 with a cerebral infarct on CT scans, no specific underlying cause was found.[6] Others, however, found an association between carotid stenosis[9,10] or carotid plaque ulceration[11] and cerebral infarction. With regard to the time course of the attacks, patients with CITS were found to have a significantly longer duration of symptoms and a smaller number of attacks.[6]

If CITS, indeed, represents a specific subgroup of patients with a different vascular cause and prognosis, this could be confirmed by differences in main symptoms (eg, cortical symptoms such as dysphasia), time course (eg, mode of onset), and prevalence of general vascular risk factors. Therefore, we have prospectively investigated possible differences in risk factors or in clinical manifestations in three groups: patients with TIA with or without a relevant cerebral infarction on CT scans, and patients with a resolving (RIND) or nondisabling stroke and a corresponding infarct on CT.

PATIENTS AND METHODS

All patients in this study were entered into a multicenter clinical trial, the Dutch TIA trial, which aimed to investigate the protective effects of low-dose aspirin and atenolol administration in patients with a TIA or a nondisabling stroke. The background and design of the study have been described elsewhere.[12] In summary, patients with one or more cerebral ischemic attacks were randomized to receive between 30 and 300 mg of acetylsalicylic acid, and, using a factorial design, 1500 patients were also randomized to receive 50 mg of atenolol or a placebo. Patients with cerebral ischemia from causes other than artery-to-artery embolism, such as polycythemia, thrombocytosis, thrombocytemia, anemia, hypoglycemia, vasculitis, or a cardiac source of embolism, were excluded. Patients with minor strokes were eligible

for the trial as long as they were independent in most activities of daily living (grade 3 or better on the modified Rankin scale[13]).

For the patient's history, a checklist was used on which the symptoms were recorded in plain language.[14] The list contained a number of detailed multiple-choice questions about the nature of the symptoms as well as about the time course, including the mode of onset, synchronicity of the symptoms, duration of the attack, mode of disappearance, and the number of attacks. The list also contained information on the following vascular risk factors and vascular diseases: a history of hypertension, diagnosed by the general physician or an internist, either treated or not; a history of hyperlipidemia, diagnosed by an internist, treated or not; a history of diabetes, treated with oral or subcutaneous antidiabetics; angina pectoris; history of prior myocardial infarction; past bypass surgery; intermittent claudication; cigarette smoking, further specified as 20 cigarettes per day, more or less; and an enlarged heart, defined as a cardiothoracic ratio on chest roentgenogram of more than 0.5.

Between March 1, 1986, and March 1, 1989, a total of 3150 patients were randomized into the study. In 24 patients, the diagnosis was evidently wrong at the time of randomization (for instance, cerebral tumor, intracerebral hemorrhage, or vasculitis), and these patients were excluded from the analysis. We also excluded 54 patients for whom a CT scan was not obtained and 268 patients in whom the interval between the CT scan and the neurological symptoms was less than 24 hours (233 patients) or unknown (35 patients). Of the remaining patients, we excluded 638 patients with symptoms suggesting ischemia in the posterior fossa (at least one of the following: rotatory dizziness, nausea, problems with swallowing, diplopia, imbalance, and loss of direction on moving the limbs), and 84 patients with monocular blindness.

The clinical data and CT scan findings in the remaining 2082 patients were analyzed. Six hundred six patients had suffered a TIA (symptoms completely reversible within 24 hours), 422 a RIND (symptoms lasting more than 24 hours, but completely reversed within 6 weeks), and 1054 a minor stroke (persisting symptoms or signs).

All CT scans were made at the time of entry into the study but at least 24 hours after the onset of symptoms. No follow-up scans with or without contrast media were performed. The scans were independently and blindly reviewed by at least two neurologists or by one neurologist and a neuroradiologist. In case of disagreement, a third neurologist or neuroradiologist arbitrated. Only after this were the observers given access to clinical details to assess the relevance of the CT scan abnormalities.

Cerebral infarcts were defined as well-defined radiolucent lesions and were subdivided into small deep lesions, cortical end-zone infarcts (superficial radiolucent areas, involving the cortex), and border-zone infarcts (wedge-shaped hypodensities in the boundary zone between two major cerebral arteries or between deep and superficial branches of the middle cerebral artery). Cortical end-zone infarcts were further specified as involving either the partial or complete territory of the supplying blood vessel. The size of the infarct was not measured. Small deep infarcts were further subdivided according to their location as follows: anterior limb of the internal capsule, genu, posterior limb, corona radiata, basal ganglia, thalamus, or other. The infarcts were classified as *recent* if they were hemorrhagic or showed a mass effect, as *old* if adjacent ventricles or sulci were enlarged, and as of *unknown onset* in the remaining patients. The scans were classified as showing a relevant infarct only, an irrelevant infarct only, or both relevant and irrelevant infarcts, depending on the clinical symptoms.

The data were analyzed by means of the Statistical Package for the Social Sciences and statistical software (Epistat). Yates' corrected χ^2 test was used where appropriate. Comparisons between the groups were expressed as odds ratios (ORs) (the ratio of TIA with infarct to TIA without infarct, and the ratio of TIA with infarct to stroke with infarct) with the corresponding 95% confidence intervals (CIs).[15] A level of $P<.05$ was considered statistically significant.

Table 1.—Presence and Type of Cerebral Infarction on CT in Patients With CITS or Patients With Stroke*

CT Finding	TIA (n = 606) n	(%)	Stroke (n = 1476) n	(%)	P†

RESULTS

In 79 (13%) of 606 patients with TIA and 663 (45%) of 1476 patients with RIND or persisting stroke, a relevant infarct was found on CT (Table 1). No statistically significant difference was found between the two groups as far as type of infarction.

The interval between the onset of the neurologic symptoms and CT scanning was not different for patients with TIA with or without infarction ($\chi^2=7.22$, $df=5$, $P=.39$) or for patients with CITS or patients with stroke and cerebral infarction ($\chi^2=10.16$, $df=5$, $P=.07$). Only 11 patients had hemorrhagic infarcts; these were two patients with CITS and nine patients who had experienced a stroke ($\chi^2=0.10$, $df=1$, $P=.74$).

No statistically significant differences were found with regard to sex and age among TIAs without infarction, CITS, and strokes with cerebral infarction.

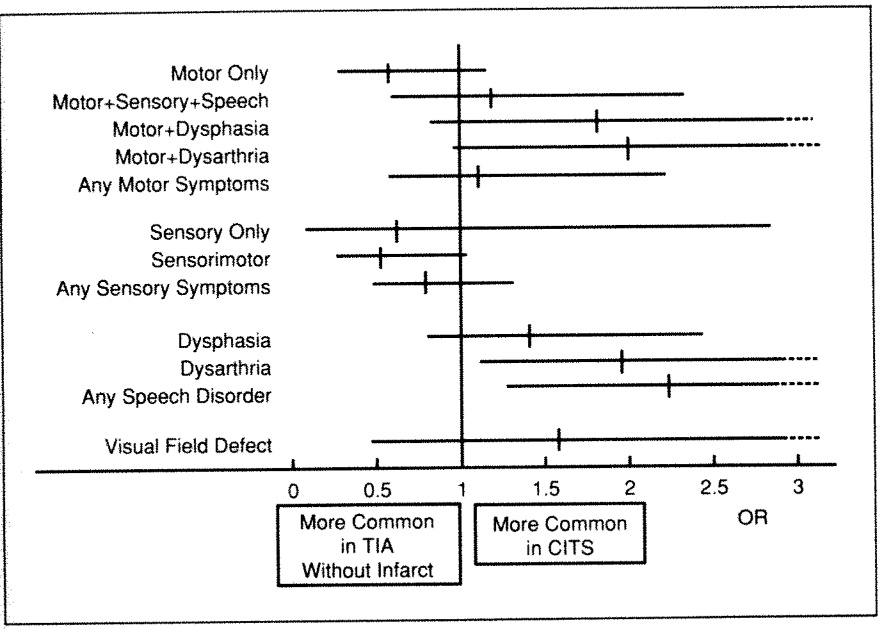

Fig 2.—Main symptom(s) in cerebral infarction with transient signs (CITS) and transient ischemic attacks (TIAs) without cerebral infarction. OR indicates odds ratio. The horizontal lines represent 95% confidence limits.

Comparisons Between Patients With TIA With or Without a Relevant Cerebral Infarct on CT

Vascular Risk Factors and Vascular Disease.—Figure 1 shows that patients with TIA and cerebral infarction more often were known to have hypertension (52% vs 33%, $P = .002$). The dotted line in the figure indicates that the upper 95% confidence limit exceeded the value of 2.5. No other significant differences between the two groups were found.

Time Course of Symptoms.—Table 2 shows the differences in time course of symptoms between patients with TIA with or without cerebral infarction. No differences were found in the mode of onset or in the number of attacks. The CITS group included more patients with attacks lasting longer than 1 hour (52% vs 34%, $P = .0003$) and, accordingly, more patients in whom the symptoms were slower to disappear (in terms of hours, 40% vs 25%; $P = .02$).

Despite this difference in time course between patients with CITS or TIA, the prediction of CT infarction on the basis of the duration of the attack proved impossible, since, in each category, the majority of patients had had a normal CT scan (Table 2).

Nature of Symptoms.—In Fig 2, the differences in main symptoms between the two groups are shown. In patients with CITS, the symptoms more often involved speech (61% vs 41%, $P = .001$), either dysarthria (difficulty in pronouncing words) (OR = 1.95; 95% CI, 1.11 to 3.42; $P = .01$) or dysphasia (difficulty in finding or understanding words) (OR = 1.39; 95% CI, 0.79 to 2.45; $P = .27$). Patients with CITS and motor symptoms more frequently described their symptom as weakness or clumsiness, whereas patients with TIA and without cerebral infarction more often complained of a "heavy" or "tired" limb (OR = 2.23; 95% CI, 0.95 to 5.48; $P = .06$). The terms used in describing visual symptoms in one hemifield (hazy, flashlights, black, or blind) did not differ significantly between the two groups.

No statistically significant differences were found in accompanying symptoms, such as headache (OR = 0.72; 95% CI, 0.33 to 1.51; $P = .45$), lightheadedness (OR = 0.81; 95% CI, 0.38 to 1.67; $P = .67$), or unconsciousness (five patients only, one of whom had an infarct on CT).

The distribution of either motor or sensory symptoms over an arm, a leg, and the face was not different between the two groups.

Comparison Between Patients With CITS and Patients With Stroke and Cerebral Infarction on CT

Vascular Risk Factors and Vascular Disease.—Figure 3 shows no differences in vascular risk factors or vascular disease between patients with CITS and patients with stroke and a demonstrable cerebral infarct.

Time Course of Symptoms.—Since the duration of the attack differed by definition between patients with CITS and patients with stroke, both the duration and rate of disappearance of symptoms were not compared. The mode of

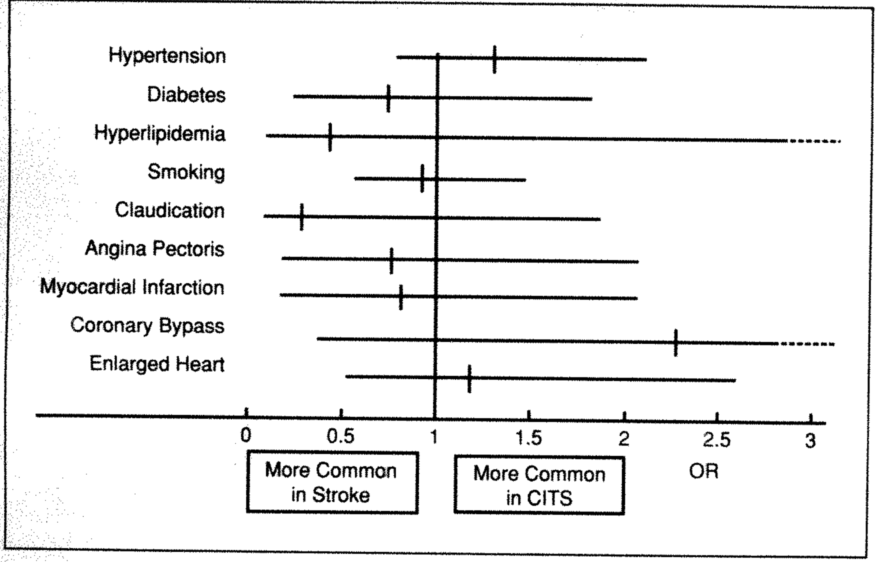

Fig 3.—Vascular risk factors and vascular disease in cerebral infarction with transient signs (CITS) and stroke with cerebral infarction. The horizontal lines represent 95% confidence limits.

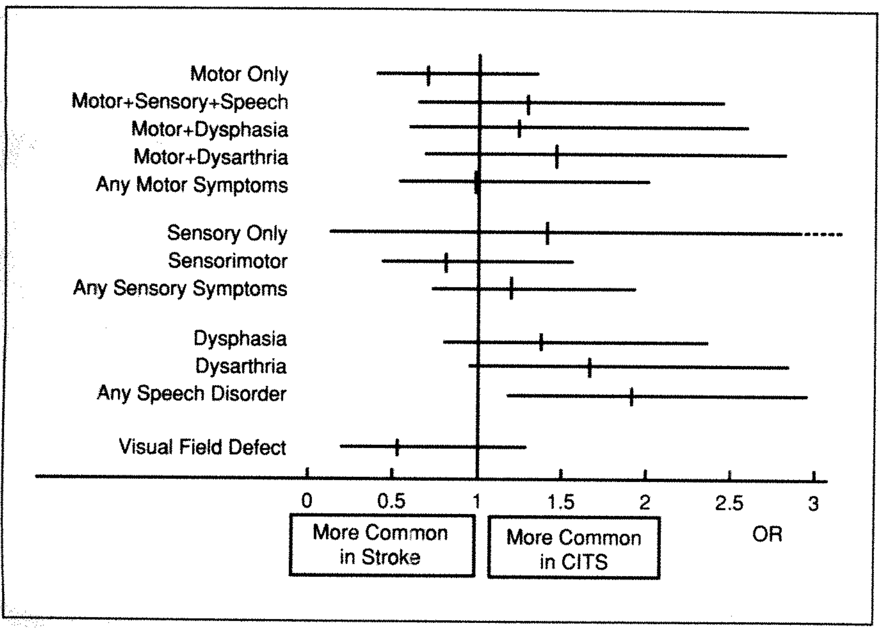

Fig 4.—Main symptom(s) in cerebral infarction with transient signs (CITS) and stroke with cerebral infarction. The horizontal lines represent 95% confidence limits.

onset was not significantly different between the two groups but tended to be slower in patients with stroke ($P=.08$). The number of attacks was significantly smaller in patients with stroke (multiple attacks, 46% vs 18%; $P<<.01$).

Nature of Symptoms.—Figure 4 shows that the differences between the two groups were very small with regard to symptoms. Patients with CITS had had a slight preponderance of speech disturbances (61% vs 45%; OR = 1.88; 95% CI, 1.14 to 3.09; $P=.01$), dysarthria in particular (OR = 1.63; 95% CI, 0.94 to 2.81; $P=.08$). No difference was found in the patients' description of visual and motor disturbances, in the distribution of motor and sensory symptoms, or in the occurrence of lightheadedness and headache as accompanying symptoms.

COMMENT

Our study shows only slight, and only a few, clinical differences between patients with TIA with or without a relevant infarct on CT. The relative preponderance of attacks exceeding 12 hours in TIAs with infarction confirms the findings of Bogousslavsky and Regli.[6] We also found a slower disappearance of symptoms in these patients, but no difference in the number of attacks. In contrast with this previous study, which showed that 84% of patients with attacks lasting more than 45 minutes had a relevant infarct on CT scans,[6] we found that the presence of cerebral infarction could not be predicted from any of the time-course variables, since in each category patients with a normal CT scan formed a large majority. The single difference in the nature of symptoms—dysarthria more often in patients with TIA and cerebral infarction—is difficult to explain and may be a chance finding. Little is known about the predictive value of individual symptoms with regard to the underlying arterial lesion or the prognosis of the patient. This issue is currently under investigation in the Dutch TIA trial.

Does CITS represent a subgroup of infarct with a specific vascular cause? This seems unlikely. First, in accordance with the findings of others,[6,11] we found that the clinical manifestations of patients with TIA with or without infarction mostly overlap. One might object that we did not perform a multivariate analysis. However, since the clinical differences that we detected in the univariate analysis were very small, the results would not have changed our ultimate conclusion. Second, others found no difference in the prevalence of cardiac emboligenic abnormalities or extracranial arterial disease between the two groups.[6] On the other hand, several investigators have reported an association between carotid stenosis[9,10] or carotid plaque ulceration[11] and cerebral infarction on CT, which suggests that CITS is associated with a more advanced degree of extracranial and intracranial arterial disease. Third, in a previous study we found no difference in the type of cerebral infarction (small deep, cortical end zone, or border zone) among patients with a TIA, RIND, or partial stroke but only in the frequency of relevant infarcts on CT.[16] Finally, newer imaging techniques such as positron emission tomography and magnetic resonance imaging may be even more sensitive than CT in documenting ischemic lesions.[17,18] Separating patients with TIA by the results of CT scanning alone therefore seems inaccurate. In addition, our study shows that the clinical differences between patients with CITS and patients with stroke and cerebral infarction were equally small, which suggests that CITS closely resembles strokes with cerebral infarction, as do TIAs without CT abnormalities.

The next step will be to investigate whether CITS represents a clinical subgroup with a specific prognosis. In the coming years, we shall analyze the outcome of events in the same cohort of patients to determine possible differences among the following four groups of patients: those with symptoms lasting less than 24 hours, those with symptoms lasting longer than that, and those with or without a relevant infarct on CT on admission.

Correction

Incorrect Data.—In the article entitled "Tuberculous Meningitis" that appeared in the December 1990 issue of the ARCHIVES (*Arch Neurol.* 1990;47:1313-1317), errors appeared in the body of Table 4 and in the footnote to that table. In the body of Table 4, in the last line under the heading "British Research Council on Admission," the following value appeared: "2.4 ± 1.7." The last line under this heading should have been left blank. In the last line under the heading "Duration of Symptoms Prior to Admission, wk," a blank space appeared. In the last line under this heading, the value of "2.4 ± 1.7" should have appeared. The first sentence to the footnote in Table 4 read as follows: "Diagnostic categories for tuberculous meningitis: seven, definite; two, probable." The sentence should have read as follows: "Diagnostic categories for tuberculous meningitis: one, definite; two, probable."

Nuclear Hemodynamic Vertebrobasilar Insufficiency

A New Approach With the Xenon Xe 133 Method

Paul Trouillas, MD; Norbert Nighoghossian, MD; Bernard Philippon, PhD

• Vertebrobasilar insufficiency is a well-known syndrome, but no corresponding hemodynamic deficit has yet been established. We propose to define nuclear hemodynamic vertebrobasilar insufficiency on the basis of an oligemia lower than 35 mL/100 g per minute in the brain stem–cerebellar region with use of the xenon Xe 133 inhalation method. Fifteen patients fulfilling this criterion underwent four-vessel angiography, computed tomography, and a standardized neurologic examination. An acetazolamide test showed poor reactivity in more than half of the patients, sometimes specifically in the vertebrobasilar area. With use of single-photon emission computed tomography and intravenous technetium Tc 99m–labeled hexamethylpropyleneamineoxime in two cases, the considerable decrease of regional cerebral blood flow in the brain stem–cerebellar region was confirmed. An excellent correlation was observed between the existence of nuclear hemodynamic vertebrobasilar insufficiency and angiographically proved arterial occlusions. The dominant nuclear oligemic zone was regularly on the side of the anatomic arterial chief lesion. Clinical manifestations included rare transient ischemic attacks (in one of 15 patients), intermittent basilar symptoms (in 15 of 15 patients), and a subacute vertebrobasilar "threatening" syndrome. Thus, imaging of a nuclear hemodynamic vertebrobasilar deficit provides an objective basis to the diagnosis of vertebrobasilar insufficiency and useful objective data for revascularization surgery.

(*Arch Neurol.* 1991;48:921-929)

The concept of vertebrobasilar insufficiency and the corresponding intermittent clinical pictures were first introduced by Denny-Brown[1,2] and Millikan and Siekert.[3]

Angiography of the vertebrobasilar system has demonstrated in vivo intracranial or extracranial arterial lesions[4,5] that are able to induce a hemodynamic deficit as first postulated by Denny-Brown.[1,2] Caplan and Rosenbaum[6] underlined the high interest about angiography to establish a topographic diagnosis of the occlusive process.

However, the existence of a real hemodynamic vertebrobasilar deficit, in the so-called clinical vertebrobasilar insufficiency syndrome, has not been demonstrated by conventional measurement of cerebral blood flow.[7]

We propose herein to identify a true posterior circulation hemodynamic deficit by defining nuclear hemodynamic vertebrobasilar insufficiency (NHVBI) as a blood flow decrease in the brain stem–cerebellar region to lower than 35 mL/100 g per minute, when blood flow is measured by the xenon Xe 133 inhalation method. This arbitrary limit was chosen because 35 mL/100 g per minute is considered a putative threshold for oligemia. In 15 patients exhibiting this hemodynamic syndrome, four-vessel angiographic findings, computed tomographic (CT) scans, and clinical data were studied. Thus, classic aspects of vertebrobasilar insufficiency were confirmed. A new clinical picture, vertebrobasilar hemodynamic "threatening" syndrome, could be observed.

PATIENTS AND METHODS

Cerebral Blood Flow Measurements

A double-headed camera (Rota camera, Siemens-France, Saint-Denis, France) equipped with two low-resolution (full width half maximum, 15 mm) and high-efficiency collimators was used to measure regional cerebral blood flow (rCBF) during a period of 2 minutes after 1.5 minutes' inhalation of ^{133}Xe. The patients were in the supine position. The inhalation gas mixture contained approximately 50 to 70 mBq/L at the first (or only) measurement, 100 to 120 mBq/L at the second measurement, and 130 to 150 mBq/L at the third measurement. Each collimator was positioned parallel to the sagittal axis of the brain. The blood flow was calculated by the method of Initial Slope Index according to Fox et al.[8] Software was designed to calculate the mean blood flow in identified oligemic areas and in standardized anatomic zones, particularly in the brain stem–cerebellar region.

Selection of Patients

The selection of patients was strictly performed on a hemodynamic basis. All kinds of neurologic patients with various symptoms underwent cerebral blood flow measurements. Patients who had had recent complete or minor strokes and who had tumors were excluded from the study. For the sake of detecting primary ischemic blood flow variations, patients with degenerative diseases and migraine were also excluded.

The definition of NHVBI was the existence of an area with an oligemia lower than 35 mL/100 g per minute in the brain stem–cerebellar region; an SD of 2.8 mL/100 g per minute, obtained from our reproductibility series, was accepted for this limit. The measurement 35 mL/100 g per minute is generally considered a possible threshold for oligemia in clinical studies,[9] although it has not yet

Reprint requests to the Neurology Service and Ataxia Research Center, Hôpital Neurologique, 59 Boulevard Pinel, 69003 Lyon, France (Dr Trouillas).

been documented in experimental studies.[10] The brain stem–cerebellar region has been chosen because its vascularization is exclusively of vertebrobasilar origin, while the occipital region recorded gets some blood supply from the carotid system. Twenty-seven consecutive patients with this hemodynamic syndrome were selected.

Of this group, 15 subjects (mean age, 62.1 ± 12.6 years) gave informed consent to undergo selective four-vessel angiography (14 times by the Seldinger technique), CT, a thorough investigation of their symptoms, and a standardized neurologic examination. This series of 15 subjects is presented herein.

Moreover, 15 age- and sex-matched patients with asymptomatic unilateral or bilateral carotid stenosis, diagnosed by Doppler ultrasonography and without detectable vertebrobasilar extracranial ultrasonographic abnormality, underwent ^{133}Xe rCBF measurement. Nineteen totally healthy controls underwent the same procedure.

Rotation and Acetazolamide Tests

Additional tests were performed in 10 patients with NHVBI. A test of rotation of the head was first done. When the rotation on one side induced clinical symptoms, this side was chosen for the test. If there was no clinical indication, rotation was randomly done on the right or the left side. A rotation position at 45° was maintained for 4 minutes, and the rCBF was then measured.

After rest, the head having returned to the neutral position, 1 g of acetazolamide was injected, and the rCBF was again measured 15 minutes later to study the vasodilatory capacity of encephalic arteries.[11]

Single-Photon Emission CT and Technetium Tc 99m–Hexamethylpropyleneamineoxime (HM-PAO) Examinations in Two Patients

In cases 1 and 4, tomographic cerebral blood flow examinations were performed with the ^{99m}Tc–HM-PAO method and with a double-headed camera (Rota camera; Micro Delta calculator, Siemens-France). A dose of 555 mBq was administered; the tomographic studies were performed 10 minutes after intravenous injection. The reconstruction procedure used is the classic filtered back projection method with a Butterworth filter, on 64 × 64 matrix.

RESULTS

The Syndrome of NHVBI

Blood flow in identified oligemic areas ranged from 22.3 to 36.4 mL/100 g per minute, and the mean value of all identified oligemic zones (the right and/or the left side) was 29.2 ± 3.7 mL/100 g per minute. When the overall brain stem–cerebellar region was considered, the mean blood flow was 33.1 ± 4.9 mL/100 g per minute on the right side and 32.9 ± 4.6 mL/100 g per minute on the left side. In the group of age- and sex-matched patients with carotid stenosis, there was no oligemic area in the posterior circulation region. The mean blood flow in the brain stem–cerebellar region was 45.1 ± 6.4 mL/100 g per minute on the right side and 46.8 ± 6 mL/100 g per minute on the left side. When compared with the mean NHVBI values, the difference was statistically significant at $P<.001$ on the left side and at $P<.02$ on the right side. The lower limit in patients with carotid stenosis (mean − 2 SDs) was 32.3 mL/100 g per minute on the right side and 34.8 mL/100 g per minute on the left side. The mean brain stem–cerebellar rCBF in healthy controls was 54.3 ± 4.3 mL/100 g per minute on the right side and 52.0 ± 5.5 mL/100 g per minute on the left side.

The patients with NHVBI could be classified into two groups according to the hemispheric rCBF values (Table 1).

Pure NHVBI (n = 6).—There was a sharp contrast between normal cerebral hemispheric blood flow (>35 ± 2.8 mL/100 g per minute) and NHVBI. Pure NHVBI was bilateral (n = 2) or unilateral (n = 4).

In index case 1 (56-year-old woman, heavy smoker), this pattern of bilateral specific NHVBI appeared clearly (Figs 1 and 2), and the oligemic phenomenon was permanent (Figs 1 and 3) when rCBF measurements were repeated. The HM-PAO CT findings confirmed the decrease in rCBF in the brain stem–cerebellar region (Figs 4 and 5). In case 4, a similar but unilateral pattern was observed with ^{133}Xe (Fig 6) and confirmed with the HM-PAO technique.

Additional tests were performed in six cases (Table 2). The rotation test showed a brain stem–cerebellar blood

Fig 1.—Case 1, xenon Xe 133 study technique, examination 1. Typical pure nuclear hemodynamic vertebrobasilar insufficiency with severe oligemia (24 mL/100 g per minute) in the left-sided brain stem–cerebellar region.

Fig 2.—Case 1, examination 2. Nuclear hemodynamic vertebrobasilar insufficiency was also observed on the right side but was less marked than on the left side. This hemodynamic syndrome was already found on this side 1 year earlier. Slight oligemic areas were observed in the parietal and frontal parasagittal regions.

Fig 3.— Case 1, examination 2. The same hemodynamic syndrome was found 1 year later, in the left-sided brain stem–cerebellar region, with a slight extension to the occipital zone.

Fig 4.—Case 1. technetium Tc 99m hexamethylpropyleneamineoxime single-photon emission computed tomographic image. This technique confirmed the existence of a considerable decrease in regional cerebral blood flow in the brain stem–cerebellar region. Note the existence of oligemia in the inferior part of the temporal lobes.

Fig 5.—Case 1, technetium Tc 99m hexamethylpropyleneamineoxime single-photon emission computed tomographic image. Note the normality of hemispheric cerebral blood flow.

Fig 6.—Case 4. Unilateral nuclear hemodynamic vertebrobasilar insufficiency with a severe oligemic zone (23.8 mL/100 g per minute) close to ischemic penumbra.

Fig 7.—Case 1, examination 2. The acetazolamide test provoked an improvement of the overall right-sided brain stem–cerebellar blood flow, but there was a zone of specific vertebrobasilar nonreactivity to acetazolamide testing.

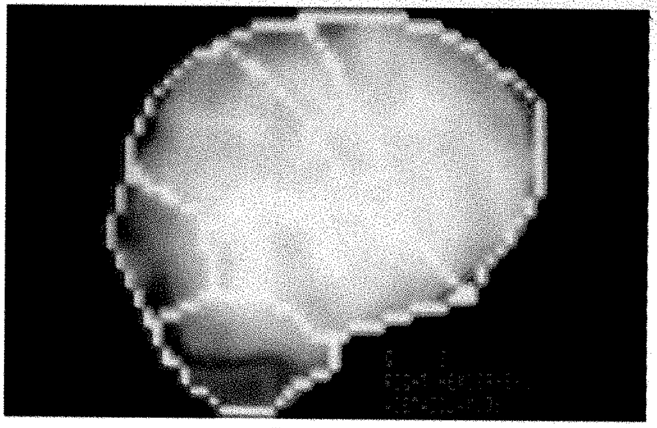

Figure 2.

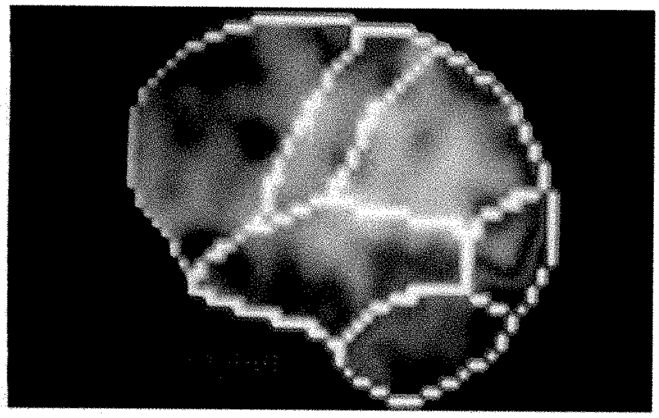

Figure 3.

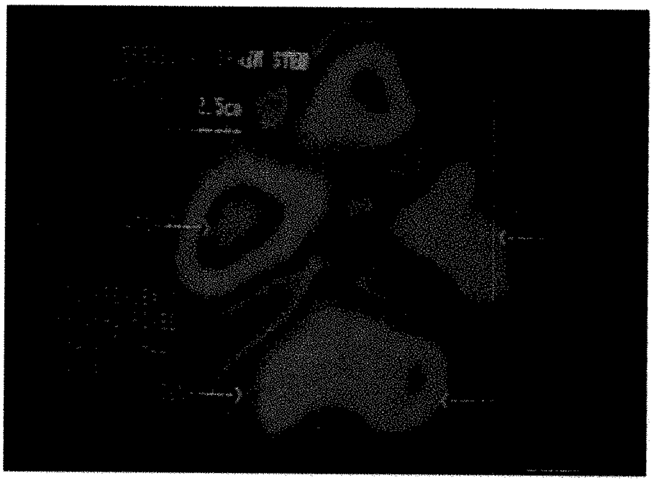

Figure 4.

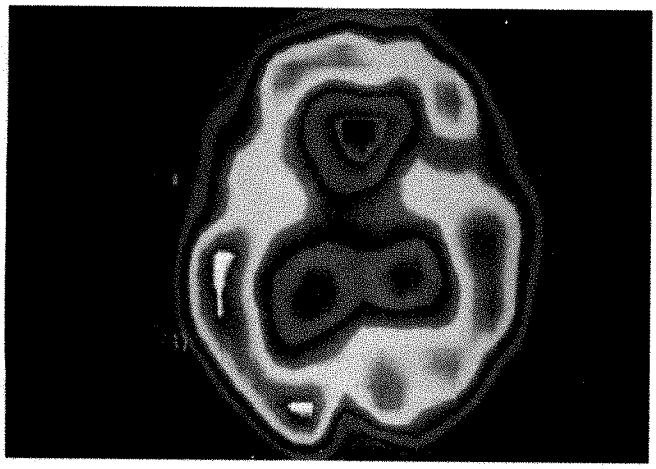

Figure 5.

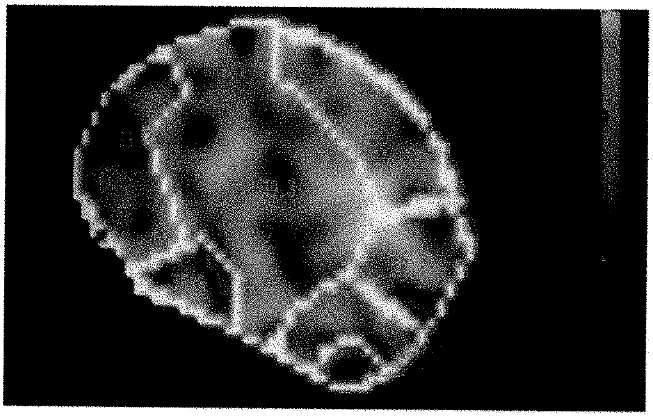

Figure 6.

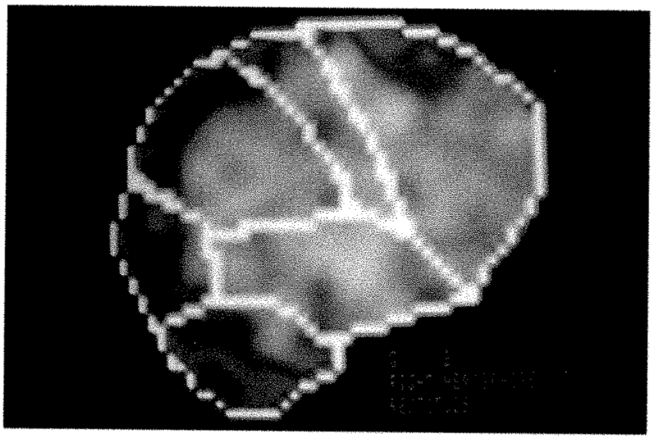

Figure 7.

flow decrease of less than 10% in three cases (Table 2). In two of these cases, the decrease took place on the opposite side to the rotation side; in the third case, it appeared bilaterally and simultaneously in the vertebrobasilar and cerebral hemispheric circulations. In a fourth case (case 1), the blood flow decrease appeared solely in the hemispheric cerebral territory.

The acetazolamide test showed poor reactivity (increase in rCBF <15%) in the brain stem–cerebellar region in four of six cases (Table 2). When the hemispheric blood flow reactivity was studied, two cases (cases 1 and 4) could be considered specific acetazolamide vertebrobasilar nonresponders. Case 1 showed a unilateral nucleus of vertebrobasilar acetazolamide-resistant oligemia on the right side (Fig 7).

NHVBI With Cerebral Insufficiency (n = 9).—In this group, NHVBI was associated with an overall decrease of hemispheric rCBF lower than 35 ± 2.8 mL/100 g per minute (Table 1). The cerebral insufficiency was either scattered in identifiable oligemic zones (five cases) or fairly global (four cases). Of four patients tested (Table 3), acetazolamide studies showed a poor reactivity (increase in rCBF <15%) in two cases. Patient 10 showed bilateral vertebrobasilar acetazolamide resistance. Rotation studies showed a global and bilateral decrease in blood flow in two cases, indicating again that the rotation test was neither vertebrobasilar specific nor side specific.

Nucleoangiographic Correlations

Table 4 presents the angiographic findings with causative data. It shows that NHVBI is strongly associated with angiographic abnormalities of the vertebrobasilar system (classification 1): 14 of 15 patients exhibited angiographically visible partial or complete arterial occlusion of the vertebrobasilar system. The abnormalities were solely extracranial in five cases, solely intracranial in three cases (Figs 8 and 9), and were both intracranial and extracranial in six cases (Fig 10). The synthesis of the 14 vertebrobasilar lesions (classification 2) is given in Table 5: the remaining patient (patient 6) had a right-sided carotid occlusion with a right posterior communicating artery steal syndrome, drawing blood from the vertebrobasilar system to the right intracranial carotid system. This patient had pure NHVBI on the left side and no hemispheric cerebral blood flow decrease on the side of the carotid thrombosis.

Table 6 shows the correlation between the side of the presumably dominant or unilateral vertebrobasilar primary lesion and the side of the dominant brain stem–cerebellar oligemia: a concordance in 10 of 13 patients was found.

The associated lesions included unilateral or bilateral lack of posterior communicating artery of the Willis polygon in five cases. Atheroma of the carotid artery was only observed in three cases of the group with NHVBI with cerebral insufficiency.

Nucleoclinical Correlations

Three types of neurologic manifestations were observed in the group of patients with NHVBI, as described below.

Vertebrobasilar Transient Ischemic Attacks.—The manifestation of vertebrobasilar transient ischemic attacks (Table 7) was classically defined as a neurologic deficit lasting less than 24 hours, subjectively considered by the patients as a true attack. It was observed in only one case and resulted in left inferior limb paresia (case 12).

Intermittent Vertebrobasilar Symptoms.—The manifestation of intermittent vertebrobasilar symptoms was defined as symptoms each lasting less than 1 hour and occurring more than three times. They could actually be repeated several times during a day or a week, for months and years. We could not classify these symptoms as transient ischemic attacks. An analysis of these symptoms is given in Table 7. Patients with NHVBI with cerebral insufficiency had the same symptoms as patients with pure NHVBI; episodic ataxia was slightly more frequent, while drop attacks and atypical falls were equally represented.

A correlation between the side of the clinically aggressive rotation and the side of the dominant brain stem–cerebellar oligemia was studied in the two groups. No clear relationship could be observed.

Vertebrobasilar Hemodynamic Threatening Syndrome.—In one case (case 8), the intermittent symptoms became virtually uninterrupted and provoked a permanent vertigo and constant unsteadiness—vestibular and cerebellar—for more than 7 days. A CT scan and a magnetic resonance image showed no infarcts or lacunae, while a marked decrease of brain stem–cerebellar blood flow was observed with associ-

*Plus sign indicates present; PICA, posterior-inferior cerebellar artery; AICA, anterior-inferior cerebellar artery; and SCA, superior cerebellar artery.

ated hemispheric oligemia. This syndrome was reversible with high doses of a parenteral vasodilatator (nafronyl oxalate [Naftidofluryl]) given for 2 weeks. A subsequent CT scan and a magnetic resonance image showed no infarcts or lacunae. The total reversibility of the syndrome with the vasodilatator was observed 1 month after onset.

COMMENT

Nuclear Vertebrobasilar Insufficiency Indicates a Definite Vertebrobasilar Hemodynamic Deficit

When coining the term *vertebrobasilar insufficiency,* Denny-Brown[1,2] clearly defined its hemodynamic importance by indicating that it corresponded to repeated "hemodynamic crisis," distinct from emboli. However, in another conception developed early by Millikan and Siekert,[3] the intermittent symptoms could also precede thrombotic or embolic basilar occlusions and were comparable with premonitory carotid transient ischemic attacks. The term *vertebrobasilar transient ischemic attacks,* widely accepted as corresponding to vertebrobasilar insufficiency,[5,12-17] thus implies a thromboembolic theory of this condition.

Thromboembolic cases do exist in vertebrobasilar disease. Yet, for strictly vertebrobasilar insufficiency, the hemodynamic theory has frequently been supported. Compression of the vertebral artery by cervical spondylosis was described by Sheehan et al[18] in 1960. Reversal blood flow through the vertebral artery[19] and hemodynamic steal of the vertebrobasilar system due to stenosis of the subclavian artery, with intermittent symptoms, were described by Contorni[20] and Fisher.[21] Carotid steal syndromes, due to internal carotid occlusion or tight stenosis, have been postulated[22] and angiographically proved.[23,24] Again, in 1970, Fisher[25] described five patients with occlusion of proximal vertebral arteries. He did not describe the clinical manifestations as vertebrobasilar transient ischemic attacks but as "transient basilar symptoms" or "transient episodes." He pointed out that these types of lesions rarely produce infarcts in the brain stem.

Moreover, the importance of circulation-influencing factors, such as orthostatic hypotension,[1,12,26,27] orthostatism without hypotension,[28] and rotation or extension of the head,[29-31] have been underlined in vertebrobasilar insufficiency.

Finally, all the successful vascular surgery in vertebrobasilar insufficiency was mainly based on the hemodynamic theory. Extracranial vertebral artery surgery has been performed since 1957.[32-36] Intracranial revascularization was first proposed by Ausman et al.[37] Extracranial-to-intracranial bypass from the occipital artery to the posterior-inferior cerebellar artery was performed.[38-40] Anastosomis of the occipital artery to the anterior-inferior cerebellar artery[41] or of the temporal artery to the superior cerebellar artery[42-44] were also proposed. Hopkins et al[45] presented their experience of revascularization and intracranial endarterectomy in 45 patients: a relief of symptoms took place in 91% of the patients, suggesting that they were of hemodynamic origin. However, in these clinical, surgical, and ra-

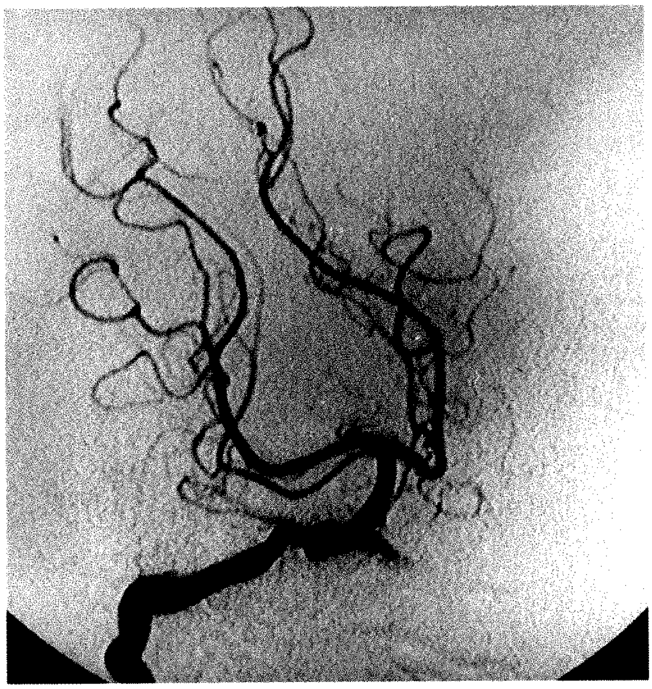

Fig 8.—Case 1. Angiographic findings included right-sided intracranial vertebral stenosis and extreme narrowing of the right posterior-inferior cerebellar artery.

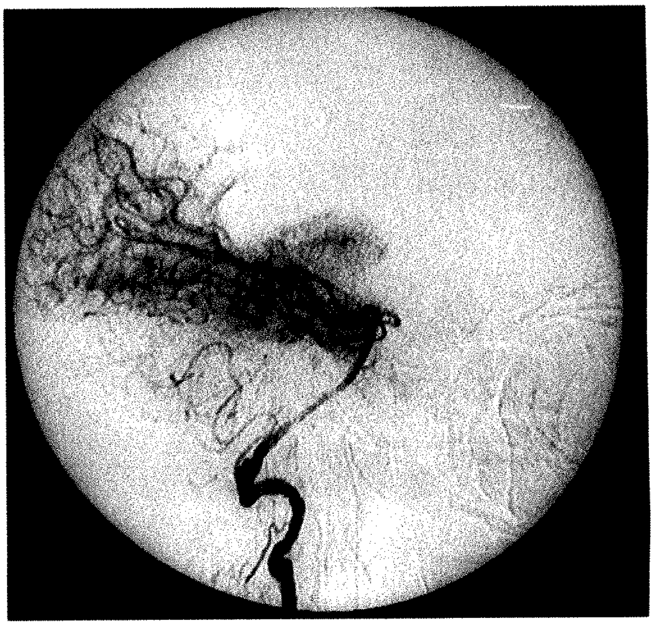

Fig 9.—Case 1. Angiographic findings (profile) included left-sided intracranial vertebral stenosis, narrowing of the left posterior-inferior cerebellar artery with radiologic oligemia of the cerebellum. Note the absence of collateral vessels between the posterior-inferior cerebellar artery and superior cerebellar artery territories.

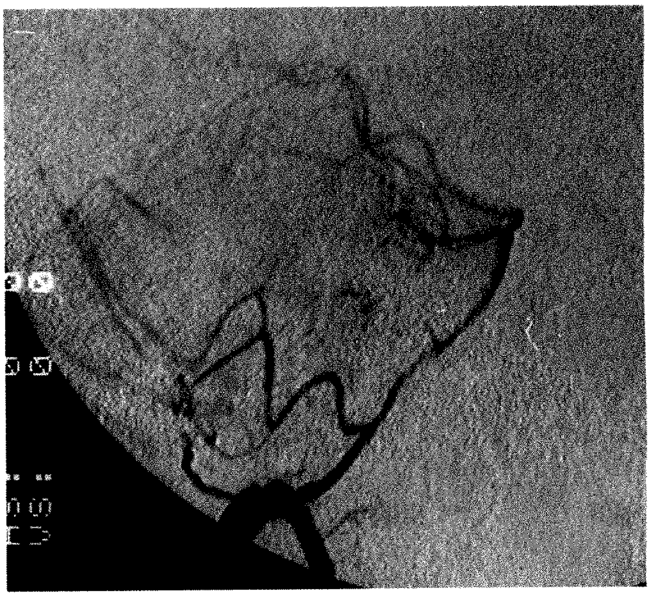

Fig 10.—Case 4. Angiographic findings on the side of nuclear vertebrobasilar insufficiency (left). Note the stenosis of the intracranial vertebral artery and the basilar artery. A distal stop of the left posterior-inferior cerebellar artery was observed. Tiny collateral vessels seemed to exist. This patient also had a partial stenosis of the two extracranial vertebral arteries at origin.

diologic approaches, the blood flow measurements were not available to give definite support to the hemodynamic theory.

Blood flow measurement does allow a hemodynamic diagnosis. The normal value of blood flow in the brain stem was determined by Brown and Donaldson,[46] with direct injection of ^{133}Xe in the vertebral artery, to be 59 mL/100 g per minute. Shirahata et al[47] mentioned a value of 54 ± 6 mL/100 g per minute with the ^{133}Xe inhalation technique. In our laboratory, the mean value in controls is 54.3 ± 4.3 mL/100 g per minute on the right side and 52.0 ± 5.5 on the left side. Naritomi et al[7] studied patients with clinical vertebrobasilar insufficiency who exhibited transient ischemic attacks and measured the cerebral blood flow after 1 minute with the ^{133}Xe inhalation technique. With the subject in the supine position, the mean brain stem cerebellar value was 97.1 ± 15.7 mL/100 g per minute, which is high. No substantial decrease of the mean brain stem–cerebellar value was observed in patients when compared with the mean value of controls. According to Naritomi et al,[7] this group of patients was characterized by a marked brain stem–cerebellar and hemispheric blood flow decrease, after orthostatic postural tilt-

ing by 30°, suggesting a generalized dysautoregulation. With use of the HM-PAO–^{99m}Tc technique, Sakai et al[48] studied a patient with spondylotic stenosis of the vertebral artery that had been angiographically confirmed. There was no decrease of the cerebellar blood flow, either in the supine position or in the orthostatic position. The rotation of the head to the left in the orthostatic position provoked a decrease of blood flow in the right occipital region and in the left cerebellar hemisphere.

In 1989, we[49] mentioned in a preliminary abstract that severe NHVBI could be diagnosed in several patients in the supine position, when ^{133}Xe inhalation blood flow measurements were performed. Preliminary angiographic and clinical findings were presented. The preliminary findings of several acetazolamide tests were also given, showing that a vertebrobasilar reactivity lacked in about half of the cases. Delecluse et al,[50] using ^{133}Xe inhalation single-photon emission CT described a patient with decreased right-sided cerebellar perfusion that did not react to acetazolamide.

In this study, we can confirm that there is a considerable group of patients with permanent NHVBI, observed with the classic blood flow measurement in the supine position. The values observed are far below the range for normal controls and even for patients with asymptomatic carotid stenosis.

The proposed threshold of 35 mL/100 g per minute was not experimentally founded. Ischemic penumbra was shown to occur at 23 mL/100 g per minute.[51] However, a growing consensus of investigators tend to consider 35 mL/100 g per minute a putative threshold of oligemia.[9] Yet, this limit of 35 mL/100 g per minute seems to be clinically valuable, because all the patients selected on this basis exhibited intermittent manifestations corresponding well to the vertebrobasilar hemodynamic crises originally described by Denny-Brown.[1,2] In these patients, the hemodynamic theory of vertebrobasilar insufficiency is thus demonstrated.

It is possible that milder levels of ischemia, greater than 35±2.8 mL/100 g per minute, might belong to the syndrome of NHVBI. Studies with a clinical basis of selection are needed to investigate this point.

This hemodynamic restriction has been documented in 10 cases by rotation and acetazolamide studies. Rotation tests showed rare specifically vertebrobasilar contralateral effects (in two of 10 patients) and global blood flow decrease (in three of 10 patients). These hemodynamic data do not confirm the classic contralateral specific vertebrobasilar effects of the rotation test but do confirm in vivo the random vertebral flow decrease induced by head rotation observed in cadavers by Toole and Tucker.[29]

Acetazolamide tests showed a poor vasodilatory capacity in the posterior circulation in more than half the patients. Some patients appeared to be specific vertebrobasilar acetazolamide nonresponders. In case 1, in which the posterior-inferior cerebellar artery was occluded, acetazolamide resistance was observed in the corresponding region.

Vascular Importance of Nucleovertebrobasilar Insufficiency

Primary arterial vertebrobasilar abnormalities have been diagnosed by angiography in 14 of 15 cases. A basilar carotid steal syndrome was also found in the 15th case. Thus, blood flow measurement of the brain stem–cerebellar region appears to be a very good indicator of the vertebrobasilar arterial circulation.

When compared with the classic angiographic series of Meyer et al[5] and Caplan and Rosenbaum,[6] our series shows a greater proportion of possibly malformative extracranial abnormalities, particularly extracranial vertebral hypoplasia, and a lower proportion of intracranial vertebral and basilar stenosis or occlusions.

The intracranial lesions in our series included unilateral or bilateral intracranial vertebral artery stenosis, as already described. The finding of vertebrobasilar insufficiency with bilateral stenosis of intracranial vertebral arteries has been reported by Ausman et al,[37,41] Roski et al,[39] Hopkins et al,[52] and Sundt et al.[53,54] Caplan[55] has recently highlighted the prominent hemodynamic permanent deficit provoked by bilateral occlusions of the intracranial vertebral artery stenosis, due to the absence of collateral vessels. In patient 1, who had such a syndrome, this hemodynamic deficit was clearly confirmed. However, our data also show that, with unilateral intracranial vertebral stenosis only, a hemodynamic deficit can occur. Absence of collateral vessels was also found in our cases, inducing a radiologic oligemia of the cerebellum.

Abnormalities of basilar branches—stenosis, narrowing, or occlusion—were also detected in our series, particularly at the level of the posterior-inferior cerebellar artery. Besides acute "basilar branch disease," as described by Fisher and Caplan[56] and Caplan,[57] we suggest that these cases, in which vertebrobasilar oligemia and clinical symptoms were demonstrated, might correspond to chronic basilar branch disease.

In several cases, distal abnormalities of the vertebrobasilar intracranial system were observed. Caplan[57] indicated that vertebrobasilar insufficiency could exist without a detectable arterial lesion and might yet have a hemodynamic origin. The effect of tobacco on distal encephalic arteries has been recently proposed by Donnan et al.[58] A general observation in the patients with intracranial vertebrobasilar and distal lesions in this series is that they were heavy smokers. One could postulate that, in these cases, the arterial stenosis or occlusions were located at the level of perforating arteries and that they were aggravated by tobacco consumption.

Nucleoclinical Correlations

Vertebrobasilar oligemia (<35 mL/100 g per minute) appears to be strongly associated with intermittent basilar symptoms (15 of 15 cases). Typical vertebrobasilar transient ischemic attacks conversely were rare (one of 15 cases). Thus, the threshold of 35 mL/100 g per minute seems to also define vertebrobasilar nonthromboembolic cases. In the colorful terms of Caplan,[55] NHVBI is related to "smoke" but not to "fire" (infarct).

The physiopathologic features of these intermittent vertebrobasilar symptoms should be discussed. Complete remission and repetition of the phenomenon suggests a purely neurophysiologic origin, consisting of short interruptions of synaptic transmission and neuronal function.

Below the limit of 35 mL/100 g per minute, a borderline hemodynamic state would exist, with an unstable metabolic compensation. The discovery of the physiologic increase of cerebellar blood flow with voluntary movements[59] might account for some of these symptoms. Insufficient posterior circulation would be unable to supply the functional increase in blood flow, so that a hemodynamic crisis due to neurophysiologic activation might then occur. Aggravation of the symptoms by orthostatism would then have an explanation other than simple orthostatic hypotension; it might also be due to the "switching on" of static cerebellar function, with a hemodynamic crisis at the level of the cerebellum and related structures.

Finally, this syndrome would be comparable with the "misery perfusion syndrome" at the hemispheric level, which includes intermittent symptoms and a compensation of oligemia by an increase of the extraction fraction of oxygen.[60]

Vertebrobasilar threatening syndrome, which was represented by one patient in our series, might correspond to the failure of the metabolic compensation of vertebrobasilar oligemia. In this field, vertebrobasilar bypass surgery finds its best theorical justification. Revascularization experiments demonstrated, in some cases, the disappearance of intermittent symptoms with improvement of the blood supply.[37,39,41,45,52-54]

In conclusion, we believe that blood flow measurement by the ^{133}Xe technique is a valuable method by which to diagnose a true hemodynamic deficit of the vertebrobasilar circulation. Imaging of a NHVBI is an easy, reproducible, and unaggressive way to confirm the clinical diagnosis of vertebrobasilar insufficiency. It might provide objective data to evaluate the effect of revascularization surgery.

This investigation was supported by research grants from the Alexis Carrel Faculty of Medicine, Lyon, France.

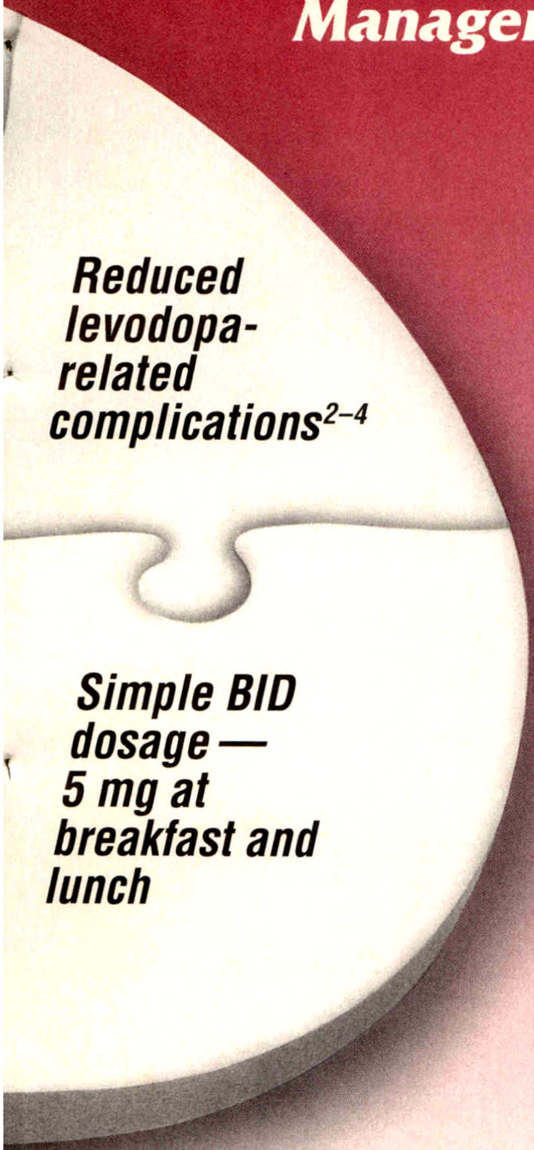
Reduces levodopa/ carbidopa dosage — usually by 10–30%[2,4†]
Favorable safety profile — lowering levodopa/carbidopa dose reduces side effects[2,3]
Selectively inhibits MAO-B to conserve endogenous and exogenous dopamine[1–3]
Stabilizes the clinical course — 71% of patients improved[3]
Improved walking, dressing; reduced drooling and tremor[2]
No tyramine ("cheese") effect at recommended dosages*

© 1991 Sandoz Pharmaceuticals Corporation/Somerset Pharmaceuticals, Inc.

ELD-1190-01 1/91

Management of Parkinson's disease...
still a puzzle



Reduced levodopa-related complications[2–4]
Simple BID dosage — 5 mg at breakfast and lunch

Benefits that provide a fitting solution

Eldepryl®

(SELEGILINE HYDROCHLORIDE)

Fits your therapeutic strategy

*Higher doses have not been shown to increase benefit and have increased the risk of side effects. Please see Dosage and Administration section of prescribing information.

†Further reduction of levodopa/carbidopa may be possible during continued selegiline therapy.

See next page for brief summary of prescribing information.

Eldepryl®

(SELEGILINE HYDROCHLORIDE)

BRIEF SUMMARY

CLINICAL PHARMACOLOGY:

The mechanisms accounting for selegiline's beneficial adjunctive action in the treatment of Parkinson's disease are not fully understood. Inhibition of monoamine oxidase, type B, activity is generally considered to be of primary importance; in addition, there is evidence that selegiline may act through other mechanisms to increase dopaminergic activity.

INDICATIONS AND USAGE:

ELDEPRYL® (SELEGILINE HYDROCHLORIDE) is indicated as an adjunct in the management of Parkinsonian patients being treated with levodopa/carbidopa who exhibit deterioration in the quality of their response to this therapy. There is no evidence from controlled studies that selegiline has any beneficial effect in the absence of concurrent levodopa therapy.

Evidence supporting this claim was obtained in randomized controlled clinical investigations that compared the effects of added selegiline or placebo in patients receiving levodopa/carbidopa. Selegiline was significantly superior to placebo on all three principal outcome measures employed: change from baseline in daily levodopa/carbidopa dose, the amount of 'off' time, and patient self-rating of treatment success. Beneficial effects were also observed on other measures of treatment success (e.g., measures of reduced end of dose akinesia, decreased tremor and sialorrhea, improved speech and dressing ability and improved overall disability as assessed by walking and comparison to previous state).

CONTRAINDICATIONS:

ELDEPRYL® (SELEGILINE HYDROCHLORIDE) is contraindicated in patients with a known hypersensitivity to this drug.

WARNINGS:

Selegiline should not be used at daily doses exceeding those recommended (10 mg/day) because of the risks associated with non-selective inhibition of MAO. (See CLINICAL PHARMACOLOGY.)

The selectivity of selegiline for MAO B may not be absolute even at the recommended daily dose of 10 mg a day and selectivity is further diminished with increasing daily doses. The precise dose at which selegiline becomes a non-selective inhibitor of all MAO is unknown, but may be in the range of 30 to 40 mg a day.

Because of reports of fatal interactions, MAOIs are ordinarily contraindicated for use with meperidine (DEMEROL & other tradenames). This warning is often extended to other opioids. Because the mechanism of interaction between MAOIs and meperidine is unknown, it seems prudent, in general, to avoid this combination.

Definitive clinical data on the concomitant use of ELDEPRYL® (SELEGILINE HYDROCHLORIDE) and fluoxetine hydrochloride (PROZAC) is not available. Death has been reported to occur following the initiation of therapy with nonselective MAOI's (NARDIL, PARNATE) shortly after discontinuation of fluoxetine. To date, this reaction has not been reported with ELDEPRYL® (SELEGILINE HYDROCHLORIDE), however, since the mechanism of this reaction is not fully understood it seems prudent, in general, to avoid this combination. Because of the long half-lives of fluoxetine and its active metabolite, at least five weeks (approximately 5 half-lives) should elapse beweeen discontinuation of fluoxetine and initiation of MAOI therapy. Based on experience with the combined use of MAOI's and tricyclic antidepressants, at least 14 days should elapse between discontinuation of an MAOI and initiation of treatment with fluoxetine.

PRECAUTIONS:

General: Some patients given selegiline may experience an exacerbation of levodopa associated side effects, presumably due to the increased amounts of dopamine reacting with super-sensitive post-synaptic receptors. These effects may often be mitigated by reducing the dose of levodopa/carbidopa by approximately 10 to 30%.

The decision to prescribe selegiline should take into consideration that the MAO system of enzymes is complex and incompletely understood and there is only a limited amount of carefully documented clinical experience with selegiline. Consequently, the full spectrum of possible responses to selegiline may not have been observed in pre-marketing evaluation of the drug. It is advisable, therefore, to observe patients closely for atypical responses.

Information for Patients: Patients should be advised of the possible need to reduce levodopa dosage after the initiation of ELDEPRYL® (SELEGILINE HYDROCHLORIDE) therapy.

Patients (or their families if the patient is incompetent) should be advised not to exceed the daily recommended dose of 10 mg. The risk of using higher daily doses of selegiline should be explained, and a brief description of the 'cheese reaction' provided. While hypertensive reactions with selegiline have not been reported, documented experience is limited. Consequently, it may be useful to inform patients (or their families) about the signs and symptoms associated with MAOI induced hypertensive reactions. In particular, patients should be urged to report, immediately, any severe headache or other atypical or unusual symptoms not previously experienced.

Laboratory Tests: No specific laboratory tests are deemed essential for the management of patients on ELDEPRYL® (SELEGILINE HYDROCHLORIDE). Periodic routine evaluation of all patients, however, is appropriate.

Drug Interactions: No interactions attributed to the combined use of selegiline and other drugs have been reported. However, because the database of documented clinical experience is limited, the level of reassurance provided by this lack of adverse reporting is uncertain. (See WARNINGS and PRECAUTIONS.)

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Studies have not been performed to date to evaluate the carcinogenic potential of selegiline hydrochloride.

Pregnancy: *Pregnancy Category C.* Insufficient animal reproduction studies have been done with selegiline to conclude that selegiline poses no teratogenic risk. However, one rat study carried out at doses as much as 180 fold the recommended human dose revealed no evidence of a teratogenic effect. It is not known whether selegiline can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Selegiline should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether selegiline hydrochloride is excreted in human milk. Because many drugs are excreted in human milk, consideration should be given to discontinuing the use of all but absolutely essential drug treatments in nursing women.

Pediatric Use: The effects of selegiline hydrochloride in children have not been evaluated.

ADVERSE REACTIONS:

Introduction: The number of patients who received selegiline in prospectively monitored pre-marketing studies is limited. While other sources of information about the use of selegiline are available (e.g., literature reports, foreign post-marketing reports, etc.) they do not provide the kind of information necessary to estimate the incidence of adverse events. Thus, overall incidence figures for adverse reactions associated with the use of selegiline cannot be provided. Many of the adverse reactions seen have been also reported as symptoms of dopamine excess.

Moreover, the importance and severity of various reactions reported often cannot be ascertained. One index of relative importance, however, is whether or not a reaction caused treatment discontinuation. In prospective pre-marketing studies, the following events led, in decreasing order of frequency, to discontinuation of treatment with selegiline: nausea, hallucinations, confusion, depression, loss of balance, insomnia, orthostatic hypotension, increased akinetic involuntary movements, agitation, arrhythmia, bradykinesia, chorea, delusions, hypertension, new or increased angina pectoris and syncope. Events reported only once as a cause of discontinuation are ankle edema, anxiety, burning lips/mouth, constipation, drowsiness/lethargy, dystonia, excess perspiration, increased freezing, gastrointestinal bleeding, hair loss, increased tremor, nervousness, weakness and weight loss.

Experience with ELDEPRYL® (SELEGILINE HYDROCHLORIDE) obtained in parallel, placebo controlled, randomized studies provides only a limited basis for estimates of adverse reaction rates. The following reactions that occurred with greater frequency among the 49 patients assigned to selegiline as compared to the 50 patients assigned to placebo in the only parallel, placebo controlled trial performed in patients with Parkinson's disease are shown in the following Table. None of these adverse reactions led to a discontinuation of treatment.

In all prospectively monitored clinical investigations, enrolling approximately 920 patients, the following adverse events, classified by body system, were reported.
